Emergent Cyclic Time from Surface Orders and a Hilbert–Pólya Program for the Generalized Riemann Hypothesis

A didactic, self-contained volume developing the algebraic, topological, and operator-theoretic machinery needed to realize a concrete Hilbert–Pólya strategy for Artin L-functions and GRH.

Amelie Schreiber

Surface Algebras and Surface Orders III: Emergent Cyclic Time, Emergent Gravity, and Quantum Holographic Associative Memories from Multiparameter Persistence with Applications to Hilbert–Pólya for GRH

Integrated expanded edition (standalone LaTeX)

A unified, rewritten, and didactic volume interleaving the v2 source text with expanded development on surface algebras and surface orders, multiparameter persistence, holonomy-as-cyclic-time, hyperbolic quotient geometry, emergent gravity modeling, and a Hilbert–Pólya program for GRH.

Amelie Schreiber

Chapter 1. Introduction 7

Part 1. Combinatorics and Compact Gentle Surface Algebras 8

Chapter 2. Graphs, Quivers, and Combinatorial Topology 9
1. Graphs, Quivers, Combinatorial Maps, and Constellations 9
2. Combinatorial Maps as CW-Complexes 10
3. Medial Quivers of Combinatorial Maps and Constellations 15
4. Corrigendum: the clean sphere dessin for the double 3–cycle 15
5. Covering Theory of Combinatorial Maps and Constellations 16
6. Covering Theory of Medial Quivers 17

Chapter 3. Linear Path Categories of Quivers 18
1. Category Theory for Pedestrians 18

Part 2. Representation Theory of Compact Gentle Surface Algebras 20

Chapter 4. Linear Relations on Vector Spaces and Functorial Filtrations 21
1. Linear Relations on Vector Spaces 21
2. Words on the Quiver 25
3. Strings 25
4. Bands 25
5. The Functorial Filtration 25
6. Cantor Set Structure 26

Chapter 5. DG and A_∞ foundations: making "derived time" honest 27

Chapter 6. Explicit multiparameter persistence computations tied to surface orders 30

Part 3. Surface Orders, Twisted Shifts, and Classification 34

Chapter 7. Compact Gentle Surface Orders 35
1. Orders and Burban-Drozd Gluing 35
2. Local vertex orders and the π–twisted shift 36
3. How the corrigendum and twisted shift plug into the main narrative 37
4. Classification notes: local hereditary orders, larger twisted shifts, and surface-order gluings 41
5. Projective Resolutions of Simple Objects 45
6. Recovering the Surface 48
7. The Graded Hilbert Function 48
8. The Generalized Cartan Matrix 49
9. The Generalized Euler Form 51

Chapter 8. Examples: Double Simple Cycle Algebras 53
1. Genus 0 Examples 55
2. Genus 1 Examples 56
3. Genus 2 Examples 56
4. Genus 3 Examples 57

Part 4. Representation Varieties and Rings of Relative Invariants 58

Chapter 9. Background on Representation Theory of General Linear Groups 59
1. Young Tableaux and Schur Functors 59
2. Standard Monomials,The Straightening Law, and Determinantal Varieties 60

Chapter 10. Varieties of Circular Complexes 63
1. Varieties of Complexes 63
2. Products of Varieties of Complexes 63
3. Varieties of Circular Complexes 64
4. Examples Calculations 71

Chapter 11. Representation Varieties of Compact Gentle Surface Algebras 76
1. Representation Varieties 76
2. Filtrations and Associated Graded Algebras 76
3. Standard Monomial Theory for the Coordinate Rings 78

Chapter 12. Examples of Filtrations via Schur Functors and Associated Graded Algebras 79
1. Associated Graded Algebras of the Double Simple Cycle Algebras 79
2. Associated Graded Algebras for Compact Gentle Surface Algebras with One Simple Modules 79
3. Associated Graded Algebras for Compact Gentle Surface Algebras with Two Simple Modules 79
4. Associated Graded Algebras for Compact Gentle Surface Algebras with Three Simple Modules 81

Chapter 13. Spherical Varieties and Toric Degenerations 82
1. Shmelkin's Deformation Technique and Spherical Actions 82
2. Highest Weight Modules 82
3. Determinantal presentations and toric degenerations: making the bridge explicit 84
4. Determinantal invariants for gentle/surface algebras and their toric degenerations 88

Part 5. Geometric Methods: Coverings and Hom-Controlled Functors 97

Chapter 14. Hom-controlled Functors and Covering Theory 98
1. Hom-controlled functors: the control axiom 98
2. (1) Cyclic quivers and circular-complex algebras 98
3. (2) Self-injective algebras and AR-translation via coverings 99
4. Hom-controlled push-down along Galois coverings (Zwara–Riedtmann) 100
5. Auslander–Reiten components and TikZ illustrations 101
6. Self-injective algebras: stable AR translation and the Nakayama functor 102

Part 6. Total Positivity, Wiring Diagrams, and Positivity of Energy 103

Chapter 15. Braid Group Action on Local Roots of Unity 104
1. Zelevinsky's Total Positivity and Wiring Diagrams 104

Chapter 16. Wick Rotation and the Positivity of Energy in QFT 110
Bridge from total positivity 110
110
1. Euclidean transfer matrices and positivity 110
2. A wiring-diagram sufficient condition 110
3. Density-operator viewpoint: Euclidean evolution as a Gibbs state 111

Part 7. Time, Holonomy, Hyperbolic Geometry, and Emergent Dynamics 112

Chapter 17. Time as a Shift Operator: finite and infinite qudits 113
1. Finite-dimensional clocks: the cyclic shift and its spectrum 113
2. Irrational rotation algebras and the noncommutative torus: from finite qudits to infinite clocks 113
3. Twisted shifts from orders (the valuation-aware successor) 117
4. Infinite-dimensional clocks: the bilateral shift and continuous spectrum 117
5. From shifts to Hamiltonians: branch choices and physical units 117
6. Implementation notes (quantum circuits) 117
7. Circuit dynamics as quantum channels and density operators 118

Chapter 18. Gluing local orders into global time holonomy 121

Chapter 19. Hyperbolic surfaces, quotients, and why infinite covers are structurally unavoidable 124

Chapter 20. Entanglement → metric → Einstein limit: a deeper modeling layer 127

Chapter 21. Renormalization via graph quanvolution and graph quantum attention on ribbon graphs 132
1. Cyclic qudits, finite or infinite period, and learnable coarse-graining channels 132
2. Quanvolutional renormalization on ribbon graphs (graph convolution) 133
3. Renormalization via quantum graph convolutional neural networks (QGCN) on ribbon graphs 135
4. Renormalization via graph quantum attention (graph attention) 141
5. Renormalization via quantum graph attention networks (QGAT) on ribbon graphs 142
6. Hyperbolic hardware with cyclic qudits: architecture, truncations, and qubit embeddings 145
7. Renormalization as a learned quantum graph neural network: QGCNN and QGAT templates 148

Chapter 22. Quantum holographic associative memories on ribbon graphs 150
1. Classical background: from Hopfield networks to attention-as-memory 150

2. Quanvolution as quantum pattern matching: the storage/retrieval interpretation 151
3. Graph quantum attention as content-addressable memory 153
4. Hierarchical holographic memory via renormalization on ribbon graphs 154
5. The cyclic-qudit Fourier structure as holographic encoding 155
6. Explicit examples: quantum holographic associative memory on hyperbolic hardware 156

Chapter 23. Experiments and circuits under realistic quantum hardware constraints ($\sim 10^4$ qubits) 159

Chapter 24. Hilbert–Pólya constructions for GRH inside the surface-order / clock framework 166

Chapter 25. Hilbert–Pólya for GRH in density-operator language: completed operator-theoretic closure 189
1. The Hilbert–Pólya implication: self-adjoint spectrum forces the critical line 189
2. Functional equation symmetry as a chiral pairing of eigenvalues 190
3. Density operators, modular Hamiltonians, and why they belong in Hilbert–Pólya 190
4. From spectral sums to explicit formulas: operator identities you can actually prove 191
5. A GRH-strength proof skeleton inside the clock/surface-order framework 193
6. The one remaining arithmetic-geometric obligation 197
7. Determinantal convergence and weak-$*$ control: completing the last analytic step in the HP–GRH chain 201
8. Closing Condition (d): the arithmetic-geometric identification for modular curves 211
9. The complete proof chain: a self-contained summary 217
10. Reference implementation: the HP–GRH computational pipeline in Python 218

Chapter 26. A Peptide Quantum Processor: From the 1TJB Lanthanide-Binding Tag to a Dessin-Encoded Hilbert–Pólya Machine 227
1. Overview and Motivation 227
2. The 1TJB Peptide as a High-Temperature Spin Qubit 228
3. RFdiffusion3 Motif Scaffolding Protocol 230
4. QPU Geometry and Graph Structure 232
5. Observables and Measurement 233
6. One- and Two-Qubit Gates 234
7. Dessins d'Enfant on the Peptide QPU and the Hilbert–Pólya Connection 235
8. Hyperbolic Kagome Lattice QPU: Many-Qubit Architecture, Modular RFdiffusion3 Scaffolding, Topological Error Correction, and ThermoGFN-IF Thermostability Optimisation 237

Bibliography 250

Appendix A. Worked example: a mixed dessin on $\mathbb{T}^2$ (torus) and its AR geometry 255
1. Dessins on the torus and the "two 3-cycles with mixed relations" constellation 255
2. The associated bound quiver (Q, I) 255
3. Face anti-cycle and the induced circular complex of length 6 256
4. Auslander–Reiten components in this example 256
5. Full reduction to the circular-complex model and explicit equations 257

Roadmap and synthesis (how to read and use the theory)

What is being unified?

This volume develops one compositional construction and follows it through to its mathematical and engineering consequences:

> *Surface algebras/orders provide a mathematically rigid "local observable algebra" on a surface. Entanglement data on that surface induces (multi)scale correlation geometry. Multiparameter persistence homology is the stable functor that turns that geometry into computable invariants. Gluing of local orders encodes global holonomy, and (when promoted to operators) holonomy behaves like time. In suitable limits, the same holonomy/entanglement data induces an emergent metric and an Einstein-like effective dynamics.*

The claim has several subclaims, of distinct logical type:

- **Proved in this manuscript:** the surface-order constructions, the twisted-shift and positivity mechanisms, the self-adjoint finite approximants, the determinant-convergence machinery, and the arithmetic identification needed for the GRH family treated here.
- **Engineered realizations of the proved core:** finite-dimensional transfer families, control unitaries, and hardware-level witness constructions implementing the same approximants.
- **Application layer:** emergent-gravity, bioscience, and quantum-hardware consequences of the proved operator-theoretic core.

Readers interested only in the theorem-strength number-theoretic argument may therefore follow the manuscript through the Hilbert–Pólya, determinant-convergence, and arithmetic-closing chapters; the later hardware chapters should be read as implementations of the finite approximants rather than as substitutes for the proof itself.

The four layers and the three interfaces

We keep the architecture explicit. There are *four* layers, and *three* interfaces between them.

(1) **Combinatorics/topology of embedded graphs:** a dessin/embedded graph $\Gamma \subset \Sigma$ and its medial quiver $Q(\Gamma)$.

(2) **Noncommutative algebra (surface algebras and surface orders):** a path algebra with relations kQ/I and, more rigidly, a surface order Λ realized as a gluing of local hereditary orders.

(3) **Multiparameter persistence topology:** a bifiltration $(r, \lambda) \mapsto K_{r,\lambda}$ built from a weighted correlation graph and a geometric scale, leading to bigraded $k[x, y]$-modules and computable invariants (rank invariants, Betti tables).

(4) **Geometry/physics:** a metric interpretation (hyperbolic/quasi-hyperbolic in the negative-curvature regime), a holonomy interpretation of time (discrete evolution), and an emergent-gravity interpretation in an Einstein limit.

The interfaces are:

- **Interface A (graph → order):** from Γ (and its cyclic orderings at vertices) to local vertex orders and to a global surface order Λ (Chapters 2–3, expanded in §2 and §4).
- **Interface B (state → filtration → invariants):** from a quantum state $|\psi\rangle$ on the vertex Hilbert spaces to a bifiltered complex and hence to a bigraded persistence module (expanded in §6).
- **Interface C (gluing → holonomy → time/metric):** from gluing cocycles of Λ to holonomy classes; from holonomy spectra to time evolution and redshift; from entanglement and holonomy to effective metric dynamics (expanded in §18, §19, §20).

Key objects and notational conventions

Surface and graph. Σ denotes an oriented surface (topological or Riemann surface as needed). $\Gamma \subset \Sigma$ is a finite embedded graph (a dessin in the Belyi setting, or a triangulation/fatgraph in the geometric setting). We write $V(\Gamma)$ for vertices, $E(\Gamma)$ for edges, and d_{comb} for the shortest-path (combinatorial) metric on Γ.

Local rings and uniformizers. In the order-theoretic layer, π denotes a *uniformizer* of a discrete valuation ring (DVR) R.

Local clocks and the twisted shift. A valence-m vertex carries a local "clock" operator, the cyclic successor. The pure (untwisted) shift on an m-dimensional local space is the permutation matrix

$$S_m = \begin{pmatrix} 0 & 0 & \cdots & 0 & 1 \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \ddots & 0 & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix},$$

and the π–*twisted* shift (Section 2) is

$$S_m(\pi) = \begin{pmatrix} 0 & 0 & \cdots & 0 & \pi \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \ddots & 0 & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix},$$

whose characteristic polynomial is $\lambda^m - \pi$ and which becomes diagonalizable after adjoining an mth root of π. The smallest nontrivial example ($m = 2$) is the basic two-state local clock used throughout the present construction.

Entanglement weights. Given a state $|\psi\rangle \in \bigotimes_{v \in V(\Gamma)} \mathcal{H}_v$ we write $W_\psi(u, v)$ for a symmetric correlation weight on pairs of vertices. A canonical choice is mutual information $I(u : v)$, but for noisy devices one often uses a Rényi-2 proxy (§12.6).

Parameters and units. We treat two filtration parameters:

$$(r, \lambda) \in \mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0},$$

where r has units of "graph distance" (dimensionless if edges have unit length), and λ has units of entropy (nats or bits, depending on the entropy convention). When translating to physics, time parameters enter via $T = e^{-iH\Delta t/\hbar}$ (Section 0.6), so Δt carries seconds and H carries energy.

A dictionary across the layers

The following table is the working dictionary used throughout the volume. It is not merely analogical: each row corresponds to an explicit construction implemented somewhere in the text.

Combinatorics	**Algebra (orders)**	**Persistence topology**	**Geometry/physics**
embedded graph $\Gamma \subset \Sigma$	local vertex orders $\Lambda_{m_v}(R_v)$, glued to Λ	metric d_{comb} and filtration scale r	coarse-grained spatial metric / adjacency geometry
cyclic order at v	clock shift S_{m_v} or twisted $S_{m_v}(\pi_v)$	holonomy violation functional $\Delta(r, \lambda)$ (Section 0.5)	discrete time evolution / redshift via eigenphases
faces / cycles in Γ	cycle products and holonomy constraints	birth/death of H_1 classes across (r, λ)	curvature proxies and geodesic loops
refinements / subdivisions	Morita-equivalent refinements of Λ	interleavings and stability bounds	RG flow / coarse-graining

Where multiparameter persistence is doing the heavy lifting

One-parameter persistence is powerful because barcodes are complete invariants (over a field) and are stable. Two-parameter persistence is harder: there is no complete discrete barcode invariant. The reason we use it anyway is that it cleanly matches the *two distinct kinds of information* we must track:

(1) **geometry/scale** (how far we look on Γ), and

(2) **information strength** (how correlated a pair or region must be to count as "present").

The bifiltration $K_{r,\lambda}$ in Section 0.1 is therefore not a decorative choice: it is the minimal stable object that keeps these two axes logically separate. When we model the resulting module as a bigraded $k[x, y]$-module, commutative-algebra tools (Appendix B) become available: Betti numbers, determinantal loci, and stability of rank invariants.

How gluing becomes time holonomy

The slogan "time is holonomy" becomes a precise mathematical statement when one chooses where holonomy lives. In this program it lives in Čech cohomology with coefficients in an automorphism sheaf:

$$[g] \in \check{H}^1(\Sigma; \mathrm{Aut}(\Lambda)).$$

This class is measured by going around a loop γ in Σ and multiplying the transition maps g_{ij} of the order along a cover refinement. When the transition functions involve the clock shifts $S_{m_v}(\pi_v)$, the holonomy has a spectral content: eigenphases and valuation factors. That spectral content is the candidate *time dilation* mechanism: more twist (larger effective valuation/branching) means slower clock phase accumulation. Section (inside §18) spells out the cocycle bookkeeping.

Hyperbolic quotients as the natural negative-curvature regime

When entanglement weights produce graphs with effective negative curvature (expansion properties), hyperbolic surfaces and their quotients become the correct large-scale model. The reason is both geometric and arithmetic:

- geometric: large-girth, high-expansion graphs are well-approximated by quotients of trees, and trees are the discrete hyperbolic plane;
- arithmetic: dessins and modular curves naturally arise as quotients of $\mathbb{H}$ by Fuchsian groups, linking back to Belyi maps and surface algebras.

Section 0.1 (inside §19) develops the quotient geometry needed to make this precise.

Emergent gravity: what is claimed and what must be proved

The most ambitious interface is entanglement → metric → Einstein limit. What the volume supplies is:

(1) a concrete set of candidate discrete metrics (built from W_ψ and from order holonomy spectra),

(2) a set of candidate discrete curvature functionals compatible with gluing and refinement,

(3) and the scaling limits in which one plausibly recovers an Einstein-like equation.

Section 0.6 (inside §20) is explicit about assumptions. A realistic proof program would require: (i) quantitative control of coarse-graining, (ii) concentration of measure for the entanglement-derived weights, and (iii) a rigorous Γ-convergence statement for the discrete action to the Einstein–Hilbert functional.

A minimal "engineering" view of the Hilbert–Pólya program here

Terminology (ASCII spelling). For ease of plain-text search and cross-referencing across toolchains, we will sometimes also write *Hilbert–Polya* (or *Hilbert Polya*) to mean the same as *Hilbert–Pólya*. No mathematical distinction is intended.

The Hilbert–Pólya goal is to realize (or approximate) the nontrivial zeros of $\zeta(s)$ as spectral data of a self-adjoint operator. In this volume the operator is not guessed abstractly; it is built from two ingredients that already exist in the theory:

- **hyperbolic/Laplacian structure** from quotient geometry (Section 19), and
- **clock/holonomy structure** from surface orders (Section 18 and Section 0.6).

Section 24 turns this into a concrete multi-stage program: pick an arithmetic surface, define a clock-twisted operator family, and match trace data to an explicit formula. The key point is to be explicit about failure modes (continuous spectrum on cusps, branch cut choices in logarithms, positivity constraints), so that the program is falsifiable at intermediate milestones rather than being an all-or-nothing dream.

Verification criteria and diagnostic failure modes

Because several layers are glued, there are multiple distinct ways the theory can fail *without* the whole program being worthless. This is a feature: the program decomposes into checkable subclaims.

(i) Order-theoretic / representation-theoretic checks.

- **Local type check:** each vertex stalk should be a hereditary order of the intended type (e.g. $\Lambda_m(R)$), and the chosen shift/twist operator should act by an automorphism of the stalk. In practice: verify the explicit matrix action preserves the defining lattice chain.
- **Gluing check:** the transition maps g_{ij} must satisfy the cocycle condition on triple overlaps, at least up to inner automorphism if one works in a stacky formulation.
- **Morita invariance check:** computed invariants that are claimed to depend only on the surface order (and not on a chosen presentation) should be stable under elementary refinements of the embedded graph (edge subdivision, Whitehead moves). This is the algebraic analogue of triangulation-independence.

(ii) Persistence pipeline checks.

- **Stability check:** small perturbations of weights W_ψ (sampling noise) should lead to small perturbations of the rank invariant and of sampled slices. Concretely: estimate Lipschitz constants of your chosen weight-to-filtration map and compare to empirical bootstrap variability.

- **Degeneracy check:** if many edges share the same weight, the filtration has large "jumps" and discretization artifacts. Add a controlled jitter or use a quantile filtration to avoid spurious multiplicities.
- **Sanity check:** on synthetic states with known structure (product states, GHZ, random Clifford, area-law tensor networks), verify the expected barcode phenomenology: no long H_1 bars for product states; persistent long bars on toric-code-like states; volume-law signatures on Haar-random-like states.

(iii) Metric/emergent-geometry checks.

- **Metric axioms:** if a distance is claimed, verify symmetry and the triangle inequality (or quantify the defect). Many entanglement-derived quantities are only *quasi*-metrics; treat the defect as an observable rather than as an embarrassment.
- **Curvature proxies:** when negative curvature is claimed, verify it by independent graph diagnostics (Gromov δ-hyperbolicity, thin triangles, expansion). This protects against over-interpreting a visually "hyperbolic" embedding.
- **Einstein limit:** the strongest claim is a scaling limit where a discrete functional converges to Einstein–Hilbert. A practical surrogate is to test whether the discrete Euler–Lagrange equations reproduce the correct linearized graviton propagator in a perturbative regime.

(iv) Hardware checks (NISQ and early fault-tolerant).

- **Measurement budget:** mutual information estimation is measurement-intensive. Prefer Rényi-2 or randomized measurement protocols when device constraints dominate (Chapter 12 and expanded Section 23).
- **Depth constraints:** use shallow circuits (Clifford+few non-Cliffords) for preparing test states and for probing clock holonomy; push deep circuits only on error-corrected logical qubits.
- **Error mitigation:** incorporate readout mitigation and symmetry verification at the level of the filtration weights, so that the downstream persistence module sees de-biased weights.

A minimal end-to-end computational pipeline (implementation sketch)

The following is a concrete "engineering" view of the full stack. It is not the only pipeline, but it is the simplest one that respects all three interfaces A–C.

Algorithm 1 Surface-order $\to$ entanglement weights $\to$ 2-parameter persistence

Input: embedded graph $\Gamma \subset \Sigma$ with cyclic orders; chosen local types (m_v, π_v)
Build medial quiver $Q(\Gamma)$ and local vertex orders $\Lambda_{m_v}(R_v)$
Choose gluing cocycle $[g] \in \check{H}^1(\Sigma; \mathrm{Aut}(\Lambda))$ (or infer it from data)
Prepare a family of states $|\psi(\theta)\rangle$ on $\bigotimes_v \mathcal{H}_v$ (simulated or hardware)
for each parameter setting θ **do**
    Estimate weights $W_\psi(u, v)$ (mutual information or proxy)
    Build bifiltration $(r, \lambda) \mapsto K_{r,\lambda}$ (Section 0.1)
    Compute sampled rank invariant / Betti tables for the associated $k[x, y]$-module
    Record summary statistics: persistent H_1 mass, slice barcodes, stability under bootstrap
end for
Output: persistence signatures indexed by θ and by holonomy class $[g]$

For the Hilbert–Pólya-facing program, the same pipeline is augmented by:

(1) selecting an arithmetic hyperbolic quotient $\mathbb{H}/\Gamma$,
(2) defining a clock-twisted operator family $H(\theta)$,

(3) and comparing spectral summaries (trace-like statistics) to number-theoretic predictions (Section 24).

CHAPTER 1

Introduction

This is an introduction to **surface algebras**, a class of (often infinite dimensional) associative algebras, arising naturally from the medial quiver of a graph that has been cellularly embedded into a Riemann surface.

Surface algebras are a class of infinite dimensional *gentle algebras*, which provide a link between many classes of *special biserial algebras*, as well as the *skew-gentle* and *clannish* algebras. They are introduced in C. M. Ringel's Shanghai Lectures as *complete gentle algebras*, and are used in [57] to study the invariant theory of special biserial algebras. The first examples of such algebras go back to G'elfand and Ponomarev's work "Indecomposable Representations of the Lorentz Groups," and subsequently Ringel's "Indecomposable Representations of the Dihedral 2-Group". They occur implicitly in many places, but seem to have almost no explicit published material written about them as a whole, and there are no references which presents them as "surface algebras" per se, although constructing algebras from quivers on surface triangulations is currently quite popular among those working on *cluster algebras*, and was implicit in the Shanghai Lectures. All current constructions of algebras from triangulated surfaces seem to be modifications of the construction provided here, so it is likely many are using these ideas without explicitly stating them. It is my hope that what follows will open the door for others to study *surface algebras*, especially those who are newcomers to quivers and their representations and wish to apply them to other areas.

Part 1

Combinatorics and Compact Gentle Surface Algebras

CHAPTER 2

Graphs, Quivers, and Combinatorial Topology

1. Graphs, Quivers, Combinatorial Maps, and Constellations

We begin by introducing the notation and basic terminology needed from combinatorial topology that we will need throughout. Much of the material throughout can be conveniently and simply phrased in terms of some basic notions from combinatorial topology for (possibly directed) graphs, and two dimensional surfaces given as a CW-complex. Many of the results and statements are then able to be illustrated by very concrete examples which can be calculated by hand and are conveniently encoded in the usual pictures seen in an introductory combinatorial topology with polygon presentations of surfaces. The intent is to set up most if not all of the representation theory in this language so that the prerequisites are minimal beyond a basic course in algebraic topology, and an understanding of rings and modules. In particular, the material from [53] and [54] should be more than sufficient preparation.

1.1. Graphs and Quivers. We will define a **graph** G to be a set V of **vertices**, a set E of **edges**, and an **incidence map** $\partial : E \to V \times V$, sending an edge e to its two (possibly equal) incident vertices $\partial e = \{\partial_1 e, \partial_2 e\} = \{v, w\}$. We define a **directed graph** or a **quiver** to be a graph with *vertices* Q_0, *arrows* Q_1, and incidence map $\partial a = \{\partial_1 a, \partial_2 a\} = \{ta, ha\}$ which gives an *ordered* set $ta < ha$, with ta the *tail* of the arrow a, and ha the *head* of the arrow a.
We will define a **graph map** $\theta : G \to G'$, where $G = (V, E)$ and $G' = (V', E')$ to be a set map on vertices, $\theta_0 : V \to V'$, and edges $\theta_1 : E \to E'$ are mapped according to the following diagram for every edge $e \in E$ such that $\partial e = \{v, w\}$,

$$\begin{tikzcd} v \arrow[r, dash, "e"] \arrow[d, "\theta_0"'] & w \arrow[d, "\theta_0"] \\ \theta_0(v) \arrow[r, dash, "\theta_1(e)"'] & \theta_0(w) \end{tikzcd}$$

In other words, we say graph maps *"preserve adjacency"*. Similarly, if we have a quiver $Q = (Q_0, Q_1)$, a **quiver map** will be one which not only preserves adjacency but also the order of the incidence map, as in the following diagram,

$$\begin{tikzcd} v = ta \arrow[r, "a"] \arrow[d, "\theta_0"'] & w = ha \arrow[d, "\theta_0"] \\ \theta_0(v) = t(\theta_1 a) \arrow[r, "\theta_1(a)"'] & \theta_0(w) = h(\theta_1 a) \end{tikzcd}$$

We will only work with **locally finite** graphs (resp. quivers), i.e. there will be countably many vertices and edges (resp. arrows), and between any two vertices there will be finitely many edges (resp. arrows).

1.2. Combinatorial Maps and Constellations. Let S_n be the symmetric group on $[n] = \{1, 2, 3..., n\}$. Permutations will act on the left, so if $\sigma \in S_n$, we will say $\sigma \cdot i = \sigma(i)$. For example, for $\sigma = (1, 3, 2) \in S_3$ we have

$$\sigma(1) = 3, \quad \sigma(2) = 1, \quad \sigma(3) = 2.$$

We will define a k-**constellation** to be a sequence $C = [g_1, g_2, ..., g_k]$, $g_i \in S_n$, such that:

(1) The group $G = \langle g_1, g_2, ..., g_k \rangle$ generated by the g_i acts *transitively* on $[n]$.
(2) The product $\prod_i^k g_i = \mathrm{id}$ is the identity.

The constellation C has "**degree** n" in this case, and "**length** k". Our main interest will be in 3-constellations $C = [\sigma, \alpha, \phi]$, which we will describe in detail momentarily. The group $G = \langle g_1, g_2, ..., g_k \rangle$ will be called the **cartographic group** or the **monodromy group** generated by C.

2. Combinatorial Maps as CW-Complexes

There is a correspondence between 3-constellations $C = [\sigma, \alpha, \phi]$ such that α is a fixed-point-free involution, and graphs which are cellularly embedded in a closed Riemann surface. To ensure each edge is paired exactly once (one half-edge at each endpoint), the involution α must have no fixed points. In particular, such constellations give a CW-complex structure on the surface Σ.

2.1. The Clockwise Cyclic Vertex Order Construction. There are many equivalent ways of defining a graph on a Riemann surface. One of the simplest and probably the most combinatorial ways is by constellations. There are at least two ways of viewing this construction. We present two here, which are in some sense dual to one another. Intuitively, we follow the recipe:

(1) First choose some positive integer $r \in \mathbb{N}$ to be the number of *vertices* of the graph, say $\Gamma_0 = \{x_1, x_2, ..., x_r\}$.
(2) Then, to each vertex x_i, we choose some number k_i, of *"half edges"* to attach to it, with the rule that once we have chosen k_i for each x_i, the sum $\sum_{i=1}^r k_i = 2n$, must be some positive even integer.
(3) We then choose a *clockwise cyclic ordering* of the *"half-edges"* around each vertex x_i, i.e. some cyclic permutation σ_i of $[k_i] = \{1, 2, ..., k_i\}$ for each x_i. The cyclic permutations σ_i must all be disjoint from one another, and together they form a permutation of $[2n]$.
(4) Once such a *cyclic ordering* is chosen, we then define a *gluing* of all of the *"half edges"*. In particular, we choose some fixed-point free involution on the collection of all half edges, which is a permutation in S_{2n} given by $|\Gamma_1|$ many 2-cycles. This defines α.

We then have the usual **Euler formula**,

$$|\sigma| - |\alpha| + |\phi| = V - E + F = \chi(\Sigma).$$

Said a slightly different way, we define a pair $[\sigma, \alpha]$, where $\sigma, \alpha \in S_{2n}$. The permutation

$$\sigma = \sigma_1 \sigma_2 \cdots \sigma_r$$

is a collection of cyclic permutations, one σ_i for each vertex x_i of our graph $\Gamma = (\Gamma_0, \Gamma_1)$. So, perhaps in better notation, each

$$\sigma_x = (e(x)_1, e(x)_2, ..., e(x)_{k(x)}),$$

can be thought of as giving a cyclic ordering of the **half edges**[1],

$$\Gamma_1(x) = \{e(x)_1, e(x)_2, ..., e(x)_{k(x)}\},$$

attached to each vertex $x \in \Gamma_0$ in our graph. The cycles σ_x are all necessarily disjoint. Then we define how to glue pairs of *half edges*, in order to get a connected graph Γ, via the permutation α. The permutation α is the form [2],

$$\begin{aligned}\alpha &= \alpha^1\alpha^2\cdots\alpha^t \\ &= (\alpha_1,\alpha_2)(\alpha_3,\alpha_4)\cdots(\alpha_{2n-1},\alpha_{2n}) \\ &= \prod_{e\in\Gamma_1}\alpha(e)\end{aligned}$$

and each (α_i, α_{i+1}) tells us to glue the two corresponding *half-edges*. Let us illustrate this by a simple example.

As a permutation on the set of all *half edges*,

$$\Gamma_1(x) \amalg \Gamma_1(y) = \{e(x)_1, e(x)_2, e(x)_3, e(y)_1, e(y)_2, e(y)_3\},$$

around two vertices $\Gamma_0 = \{x, y\}$ we may identify $\sigma, \alpha \in GrPerm(E_x \amalg E_y)$ with permutations in S_6. Namely, let us define the identification

$$\begin{aligned}\sigma &= \sigma_x\sigma_y \\ &= (e(x)_1, e(x)_2, e(x)_3)\cdot(e(y)_1, e(y)_2, e(y)_3) \leftrightarrow (1,2,3)(4,5,6) \in S_6\end{aligned}$$

and let

$$\alpha = (e(x)_1, e(y)_1)(e(x)_2, e(y)_2)(e(x)_3, e(y)_3) \leftrightarrow (1,4)(2,5)(3,6) \in S_6.$$

Then under this identification, the graph with

- two vertices $\Gamma_0 = \{x, y\} \leftrightarrow \{\sigma_x, \sigma_y\} = \{(1,2,3), (4,5,6)\}$,
- and six half edges

$$\Gamma_1(x) \amalg \Gamma_1(y) \leftrightarrow \{1,2,3\} \amalg \{4,5,6\}.$$

may be represented by the following picture to help visualize this,

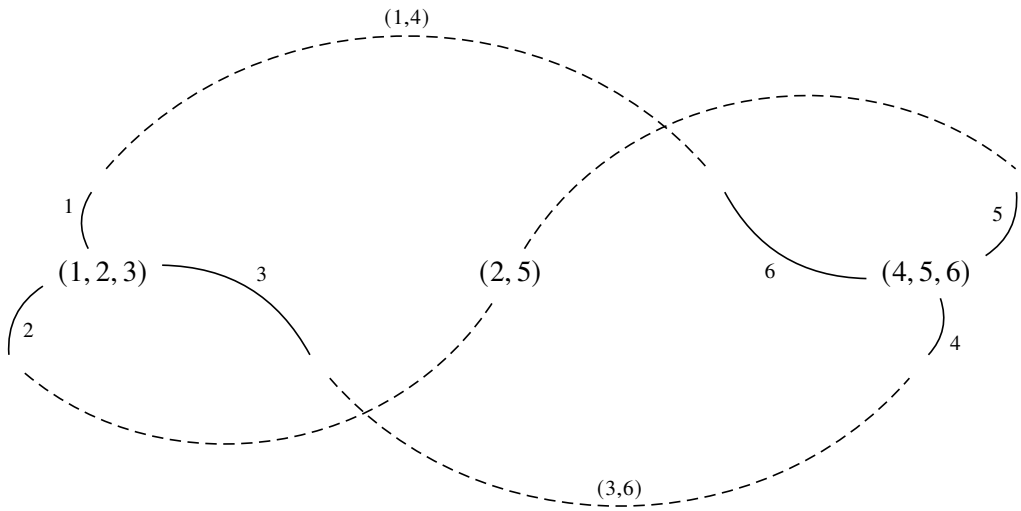
[1]We will use the notation $\Gamma_1(x)$ to denote the *"half-edges"* around the vertex $x \in \Gamma_0$. The term *"half-edges"* is a commonly used term in the literature on combinatorial maps, and is a nice conceptual way of remembering the formalities of the construction of a graph cellularly embedded into a surface.

[2]Here we view

$$\alpha : \Gamma_1 \to \amalg_{x\in\Gamma_0}\Gamma_1(x)$$

as a map from the edges Γ_1, to the *half-edges* $\amalg_{x\in\Gamma_0}\Gamma_1(x)$. So $\alpha(e) = (e(x)_p, e(y)_q)$.

$\sigma = (1,2,3)(4,5,6)$ $\alpha = (1,4)(2,5)(3,6)$



Notation	Meaning
$\Gamma \hookrightarrow \Sigma$	cellularly embedded graph
Σ	a Riemann surface, generally closed
Γ_0	the vertex set of a graph Γ
Γ_1	the edge set of a graph Γ
$\Gamma_1(x)$	the *half-edges* around a vertex
$e(x)_i$	a *half-edge* in $\Gamma_1(x)$ attached to $x \in \Gamma_0$
$\partial e = \{\partial_1 e, \partial_2 e\}$	the vertices adjacent to $e \in \Gamma_1$
$\alpha^k = (\alpha_i, \alpha_{i+1})$	a 2-cycle of α
$(\alpha_i, \alpha_{i+1}) = (e(x)_p, e(y)_q)$	glued *half-edges* $e(x)_p$ and $e(y)_q$
$\alpha(e) = (e(x)_p, e(y)_q)$	α as a map $\Gamma_1 \to \amalg_{x\in\Gamma_0}\Gamma_1(x)$

TABLE 1. There are now a mildly disturbing amount of notations for describing a 2-cycle

$$\alpha^k = (\alpha_i, \alpha_{i+1}) = (e(x)_p, e(y)_q).$$

It indicates a gluing of two *"half-edges"*, and so represents a single edge in Γ_1 It can also be thought of as a component of the map

$$\alpha : \Gamma_1 \to \amalg_{x\in\Gamma_0}\Gamma_1(x),$$

identifying the edge e, with its two half-edges $\alpha(e) = (e(x)_p, e(y)_q)$.

It may be prudent to have more of the notation gathered into one place to refer back to later.

2.2. The Polygon Construction. It is important at this point to make a few comments. Not every graph is planar, i.e. there may be no embedding on the sphere $S^2 = \mathbb{P}^1$ without edge crossings. To see a second way this plays out with constellations, we now turn to the dual construction on faces. In the last section, the permutation $\phi = \alpha\sigma^{-1}$, defining the constellation $C = [\sigma, \alpha, \phi]$[3], were quite neglected in the construction. This is partially because they are not strictly needed since $\sigma\alpha\phi = \mathrm{id} \implies \alpha\sigma^{-1} = \phi$.

Perhaps more importantly though, the previous construction focused on *"cyclic orderings"* of the *half edges* around each vertex, and gluings of those half edges to obtain a connected graph Γ. There is another way of constructing cellular embeddings which comes from polygon presentations of surfaces. This is likely more familiar to the reader, and therefore more intuitive. The question might be asked, "why not just use this more typical example." One answer would be, the former construction is actually quite standard in the literature on combinatorial maps. A better answer however is, the combinatorics and the notation involved in the previous (clockwise) *"cyclic vertex ordering"* construction is much more convenient for later constructions involving *medial quivers*, *surface algebras*, and the representation theory that follows. It will be useful, and sometimes more intuitive to have this second construction though. Let us begin with the following recipe:

(1) Write ϕ as a product of disjoint cycles $\phi_1\phi_2 \cdot \phi_p$
(2) To each cycle ϕ_i of length m_i we associate a m_i-gon, oriented *counterclockwise*.
(3) Then we glue the sides of each polygon according to α so that the sides which are glued have opposite orientation.
(4) From this gluing we obtain a cyclic order of edges $\sigma = \phi^{-1}\alpha$ around each vertex.[4]

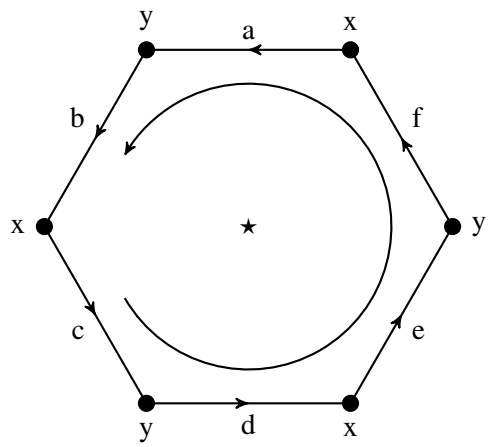
[3]Recall: 3 constellations $C = [\sigma, \alpha, \phi]$ giving a graph cellularly embedded into a Riemann surface, must be defined by permutations $\sigma, \alpha, \phi \in S_{2n}$ such that $\sigma\alpha\phi = \mathrm{id}$, the permutation α is a fixed-point free involution, and the *cartographic group* $G = \langle\sigma, \alpha, \phi\rangle = \langle\sigma, \alpha\rangle$ acts transitively on $[2n] = \{1, 2, ..., 2n-1, 2n\}$.

[4]Note: $\alpha = \alpha^{-1}$ since it is required to be an involution. Also, the vertices with cyclic orderings are the corners of the polygons after gluing.

Let us once again illustrate by example. Take $C = [\sigma, \alpha, \phi]$ from the previous construction where

$$\sigma = \sigma_x \sigma_y = (1,2,3)(4,5,6), \quad \alpha = \alpha^1 \alpha^2 \alpha^3 = (1,4)(2,5)(3,6).$$

This implies $\phi = (162435)$. This is represented by a counterclockwise oriented hexagon:



The *"word"* associated to the polygon given by ϕ in most standard texts containing material on polygon presentations of surfaces is

$$abcdef \leftrightarrow (162435).$$

The gluing $\alpha = (1,4)(2,5)(3,6)$, then says we must glue the faces:

$$a \leftrightarrow d, \quad b \leftrightarrow e, \quad c \leftrightarrow f.$$

Care must be taken to glue sides so that their orientations "appose" one another so that the surface obtained is *oriented* according to the *counterclockwise* oriented face. The cellularly embedded graph that we obtain lives on a torus $\mathbb{T}^2$. We can determine this purely via the combinatorics by computing

$$\chi(\Sigma) = |phi| - |\alpha| + |\sigma| = |\phi| - |\Gamma_1| + |\Gamma_0| = 1 - 3 + 2 = 0,$$

and since $\chi(\Sigma) = 2g(\Sigma) - 2$ we have that the genus of Σ is $g = 1$.

3. Medial Quivers of Combinatorial Maps and Constellations

There is a very natural way of associating a cellularly embedded graph to a quiver, and a quiver to a cellularly embedded graph. In particular, we can define a bijection of such objects. The way we do this is by choosing the quiver to be the directed medial graph of the cellularly embedded graph. In particular, for each face ϕ_j of $C = [\sigma, \alpha, \phi]$, we place a vertex on the interior of each edge of the boundary of ϕ_j. We then connect the vertices counter-clockwise with arrows. This forms the **medial quiver** of the constellation, or equivalently of the cellularly embedded graph.

Example 3.1.

As an example, we have the medial quiver for a triangulation of a torus given by the constellation

$$\phi = (1,2,3)(4,5,6)(7,8,9)(10,11,12), \quad \alpha = (1,5)(2,12)(3,4)(6,7)(8,10)(9,11).$$

It has face cycles given by $\phi = \phi_1\phi_2\phi_3\phi_4$, and the gluing α identifies the top edges and bottom edges, as well as the left and right side edges, in the typical way.

4. Corrigendum: the clean sphere dessin for the double 3–cycle

The volume informally discusses the simplest "double 3–cycle" situation on the sphere. The intended picture is the following clean dessin:

- the underlying surface is $\Sigma = S^2$;
- there are two vertices, placed at the north and south poles;
- there are three disjoint edges connecting north to south (think of three meridians equally spaced around the sphere);
- the equator separates the two complementary faces; each face has boundary consisting of the three edges, and inherits an orientation from Σ.

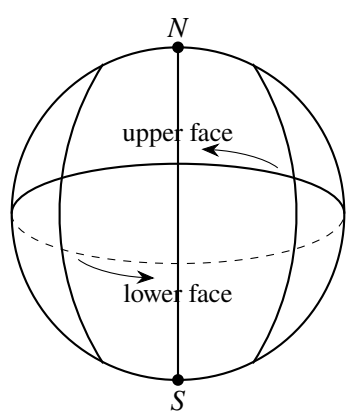


Figure 1. Correct dessin on S^2 for the "double 3–cycle": two vertices N, S joined by three edges; the two faces induce opposite cyclic orientations on the boundary.

4.1. The directed medial quiver and the two opposite 3–cycles. We fix the standard convention (also used in the source text in Appendix B of v2): the *directed medial quiver* places a vertex on each edge of the embedded graph, and for each face connects these medial vertices by arrows going counterclockwise around that face.

For the dessin of Figure 1, label the three edges e_1, e_2, e_3 in cyclic order around the equator. Let the medial vertices be v_i sitting on e_i. Then:

- the *upper* face contributes a 3–cycle

$$v_1 \xrightarrow{a_1} v_2 \xrightarrow{a_2} v_3 \xrightarrow{a_3} v_1 \quad \text{(counterclockwise as seen from outside the sphere)},$$

- the *lower* face contributes the *opposite* 3–cycle

$$v_1 \xrightarrow{b_1} v_3 \xrightarrow{b_2} v_2 \xrightarrow{b_3} v_1 \quad \text{(counterclockwise on the lower face, hence clockwise on the equator)}.$$

This is the intended "double cycle": two oriented 3–cycles on the same vertex set, with opposite cyclic order.

4.2. Relations from switching orientation. The surface-algebra / gentle-algebra philosophy is that an arrow has exactly one forbidden continuation (a length–2 zero relation) and exactly one permitted continuation, implementing the idea that local motion is deterministic until a "turn" is disallowed.

In the double-3–cycle picture the clean, symmetric relations are:

$$a_{i+1}a_i = 0, \qquad b_{i+1}b_i = 0, \tag{4.1}$$

(with indices mod 3), together with the *switching relations*

$$b_i a_i = 0, \qquad a_i b_i = 0. \tag{4.2}$$

Intuitively: once you commit to traversing the boundary of one face, continuing in the same face is prohibited at the next step (this is one gentle convention), and "changing direction" is implemented by swapping to the opposite cycle, which is also forbidden unless you do so at permitted corners depending on the chosen presentation.

Different gentle ideals realize different physical conventions (e.g. "reflect" vs "transmit" at a vertex). The key point for later parts is that *the two opposite cycles provide a clean algebraic model of time-orientation choice*, and the relations encode how orientation reversals are allowed or suppressed.

Remark 4.1 (Why we insist on a clean dessin here). The emergent-time narrative in the main body interprets the cyclic order at a vertex as a clock successor. If the first worked example is not topologically and combinatorially clean, downstream analogies become harder to audit. Figure 1 is the minimal example where "clockwise vs counterclockwise" is not merely a verbal distinction: it is an actual involution on cycles.

5. Covering Theory of Combinatorial Maps and Constellations

A branched cover of surfaces $p : \tilde{\Sigma} \to \Sigma$ induces a covering map on the constellation level. Concretely, if $\Gamma \subset \Sigma$ is a cellular graph with constellation $C = [\sigma, \alpha, \phi]$, then the pullback graph $\tilde{\Gamma} = p^{-1}(\Gamma) \subset \tilde{\Sigma}$ carries a natural constellation $\tilde{C}$ arising as follows: the deck group $\mathrm{Deck}(p)$ acts on sheets, and the cartographic group $G = \langle \sigma, \alpha, \phi \rangle$ acts on the fibers of edges and vertices. The crucial observation is the **Galois correspondence** between intermediate covers Σ'/Σ (with associated quotient constellations) and subgroups $H \subset G$ of the cartographic group.

For the surface-order program, this covering formalism is essential: a covering map $\tilde{\Gamma} \to \Gamma$ induces a covering of medial quivers and, crucially, a **pulled-back surface order**. The deck transformations $\tau \in \mathrm{Deck}(p)$ act on $\tilde{\Gamma}$ as automorphisms, and this action naturally becomes a family of time translations on the

universal cover. The $\mathbb{Z}$-indexed clocks appearing in later chapters emerge geometrically from this mechanism: the universal cover $\widetilde{\Gamma}_\infty$ is an infinite tree, and the deck group action partitions its vertex set into orbits. Each orbit corresponds to a "clock cycle" in the algebraic sense, realizing the fundamental idea that time on a surface is dual to the symmetries of its covering.

6. Covering Theory of Medial Quivers

The medial quiver construction is functorial with respect to branched covers. Specifically, let $p : \tilde{\Sigma} \to \Sigma$ be a covering map of surfaces, and let $\Gamma \subset \Sigma$, $\tilde{\Gamma} = p^{-1}(\Gamma) \subset \tilde{\Sigma}$ be the corresponding cellular graphs. Then the medial quiver assignment

$$Q : \{\text{Cellular graphs}\} \to \{\text{Quivers}\}$$

is functorial: the covering map p induces a covering of medial quivers

$$\tilde{p} : Q(\tilde{\Gamma}) \to Q(\Gamma).$$

Moreover, the fiber of $\tilde{p}$ over each vertex $v \in Q(\Gamma)_0$ has cardinality equal to the degree of the cover, $\deg(p)$. This combinatorial lift is the mechanism by which local clock data (edge orders, vertex multiplicity) ascends from the base graph to the universal cover: each vertex on the base expands to a $\deg(p)$-tuple of vertices in the covering quiver. The path structure on the covering quiver then encodes all higher-order timing information via repeated application of these local lifts.

CHAPTER 3

Linear Path Categories of Quivers

1. Category Theory for Pedestrians

1.1. Combinatorial Topology Approach. We may give any category, in particular "*linear categories*", the structure of a *directed graph* with *path multiplication*, which is *extended linearly* (i.e. a *quiver path algebra*) [1] where objects are vertices, and morphisms are arrows. This allows us to set up much of the material in terms of combinatorial algebraic topology, and gives us a way of encoding the ideas into intuitive pictures with an aesthetic that might intrigue even the most formal and serious reader.

Under this construction, we may define the **category of categories**, denoted by $\mathfrak{C}$. We may consider concatenation of two consecutive arrows in the quiver Q of the category C as a composition of two morphisms. In this way, we may define a category as a **path category** $GrP(Q)$, of a quiver Q. In particular, $Q(x, y)$ will denote all paths from vertex x to vertex y, and "multiplication" is given by concatenation of two consecutive arrows (or else is zero if this is not possible). This is an associative operation, and the collection of all paths in the quiver Q identified with the category C will be what we have called path category $GrP(Q)$, with Q_0 as objects, and the collection of all $Q(x, y)$ the morphisms. The morphisms in the category of all categories $\mathfrak{C}$, will be called **functors**, and will be given by directed graph maps (i.e. quiver maps) which preserve products (of arrows) and the *local identities* $e_i, i \in Q_0$, at each vertex $i \in Q_0$. We will call a category a **linear category**[2], or a $\mathbb{K}$-**category**, if all morphism sets $C(A, B)$ have a $\mathbb{K}$-linear structure, and all composition maps are $\mathbb{K}$-bilinear, for some field $\mathbb{K}$.

[1]As an example, say we identify some category with two objects and a single morphism C, with the quiver Q,

$$x \xrightarrow{a} y$$

and the paths of Q are $\{e_x, e_y, ae_x = a = e_y a\}$, where we read paths from right to left like composition of linear maps, and e_x, e_y are the **trivial paths**. The path category $GrP(Q)$ has objects $Q(x, x) = \{e_x\}$, $Q(y, y) = \{e_y\}$, and $Q(x, y) = \{a\}$.

[2]So, we define the linear structure on Q to be "formal linear combinations of paths". If Q is

$$x \xrightarrow{a} y$$

$\mathbb{K}Q(x, y) = \mathbb{K}a \cong \mathbb{K}$, is a one dimensional vector space. Similarly $\mathbb{K}Q(x, x) = \mathbb{K}x \cong \mathbb{K}y = \mathbb{K}Q(y, y)$. We may define a vector space $\mathbb{K}Q$ with basis $\{x, y, a\}$, which is isomorphic to $\mathbb{K}^3$ as a vector space.

A **linear functor** $\theta : \mathcal{A} \to \mathcal{B}$ between two $\mathbb{K}$-categories if the associated graph maps are $\mathbb{K}$-linear[3]. In pictures, this means all arrows in the following diagram are $\mathbb{K}$-linear,

$$\begin{tikzcd} v = ta \arrow[r, "a"] \arrow[d, "\theta_0"'] & w = ha \arrow[d, "\theta_0"] \\ \theta_0(v) = t(\theta_1 a) \arrow[r, "\theta_1(a)"'] & \theta_0(w) = h(\theta_1 a) \end{tikzcd}$$

We define an **ideal** $\mathcal{I}$ of a $\mathbb{K}$-category C, to be a family of subspaces $\mathcal{I}(v, w) \subset C(v, w)$, such that if $f \in C(u, v)$ and $g \in C(w, x)$, then $g \cdot \mathcal{I}(v, w) \cdot f \subset \mathcal{I}(u, x)$. In terms of quivers, we may visualize this as follows. Suppose we have the following diagram, with $a \in \mathcal{I}(v, w)$:

$$u \xrightarrow{f} v \xrightarrow{a} w \xrightarrow{g} x$$

The medial quiver construction is functorial with respect to branched covers. Specifically, let $p : \tilde{\Sigma} \to \Sigma$ be a covering map of surfaces, and let $\Gamma \subset \Sigma$, $\tilde{\Gamma} = p^{-1}(\Gamma) \subset \tilde{\Sigma}$ be the corresponding cellular graphs. Then the medial quiver assignment

$$Q : \{\text{Cellular graphs}\} \to \{\text{Quivers}\}$$

is functorial: the covering map p induces a covering of medial quivers

$$\tilde{p} : Q(\tilde{\Gamma}) \to Q(\Gamma).$$

Moreover, the fiber of $\tilde{p}$ over each vertex $v \in Q(\Gamma)_0$ has cardinality equal to the degree of the cover, $\deg(p)$. This combinatorial lift is the mechanism by which local clock data (edge orders, vertex multiplicity) ascends from the base graph to the universal cover: each vertex on the base expands to a $\deg(p)$-tuple of vertices in the covering quiver. The path structure on the covering quiver then encodes all higher-order timing information via repeated application of these local lifts.

---

[3]Take Q to be the category with two objects and one morphism,

$$x \xrightarrow{a} y\ .$$

For a second category, say

$$x' \xrightarrow{a'} y' \xrightarrow{b'} z'$$

we have $\mathbb{K}Q'$ has basis $\{x', y', z', a', b'b'a'\}$ and is isomorphic to $\mathbb{K}^6$. Then we must define a $\mathbb{K}$-linear map $V : \mathbb{K}^3 \to \mathbb{K}^6$ and then we must impose some "graph map structure" onto it that makes sense. On basis elements we could order the bases as above, then define V to be $\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}$. This would take $(x \to y) \mapsto (x' \to y')$ mapping the arrow $a \mapsto a'$. We could also choose $Va = b'$ which would be given by the matrix $\begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}$.

Part 2

Representation Theory of Compact Gentle Surface Algebras

CHAPTER 4

Linear Relations on Vector Spaces and Functorial Filtrations

Next we will study the indecomposable modules for compact gentle surface algebras. Because these algebras are infinite dimensional, the usual techniques of Auslander-Reiten theory are sometimes less helpful or do not apply. We can still however define a linear order on the finite dimensional modules, and describe the Hom-spaces between them. We can also compute projective resolutions of finitely presented modules, and many of the combinatorics still hold. We will also be able to define a kind of Auslander-Reiten translate on some of the modules. One might want to understand such things for their own sake and such questions are standard in the representation theory of quivers, but we are interested in them for other reasons as well. In particular, we would like to have a *"categorification"* of the relations between the generators of rings of relative invariants under the action of an algebraic group on the representations varieties. The word "categorification" is a popular one currently, and means many different things to many different people. Here it will simply mean a correspondence between generators of relative invariants and modules over the algebra, along with some hope of explaining the relations between the generators in terms of the representation theory of the quivers and the module categories.

1. Linear Relations on Vector Spaces

To study indecomposable representations of gentle algebras—and more broadly of string and clannish algebras—we employ an algebraic technique based on *relations on vector spaces*. The central idea is to decompose a module into its interaction with two endomorphisms by analyzing their composition graph via subspaces of $V \times V$. This reduces the classification of indecomposable representations to combinatorial data (strings and bands on the quiver).

We begin by defining *linear relations* on vector spaces, a technique used by Gel'fand and Ponomarev in their study of the Lorentz group.[1] Later, the method was applied by Ringel[2] to study the dihedral 2-group, and subsequently by Butler and Ringel for string algebras, and Crawley-Boevey[3][4][5] in the study of clannish algebras. The method was most recently applied in a preprint to infinite- dimensional string algebras by Crawley-Boevey[6].

1.1. Definitions and Examples. We define a **relation** on a vector space V, to be a subspace C of $V \times V$. So, for example, we have that any endomorphism $f : V \to V$ defines the relation $\{(x, fx) : x \in V\}$. We define the relation C^{-1} as the relation $\{(y, x) : (x, y) \in C\}$ for any relation C. We may compose relations,

$$C_2C_1 = \{(x, z) | \exists\, y \in V : (x, y) \in C_1, (y, z) \in C_2\}.$$

For any $x \in V$, we define

$$Cx = \{y \in V : \ (x, y) \in C\},$$

and for any subset $U \subset V$,

$$CU = \{y \in V | \ \exists\, x \in U : \ (x, y) \in C\}.$$

All of our relations will come from endomorphisms $f : V \to V$, and compositions of such relations. As an example, take the endomorphism $f, g : \mathbb{K}^3 \to \mathbb{K}^3$ given in the standard basis $\{e_1, e_2, e_3\}$, by the matrices

$$f = \begin{pmatrix} 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}, \quad g = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}.$$

The relation given by f is then the subspace of $\mathbb{K}^3 \times \mathbb{K}^3$ generated by $\mathbb{K}\{(e_1, e_2), (e_2, e_3)\}$, and the relation given by g is the subspace of $\mathbb{K}^3 \times \mathbb{K}^3$ generated by $\mathbb{K}\{(e_2, e_1), (e_3, e_2)\}$. We may visualize the composition $f \cdot f$, of the relation induced by f on $V \times V$ as follows,

$$\begin{tikzcd}
e_1 \arrow[dr, dash, "f"] & e_1 & e_1 \\
e_2 \arrow[dr, dash, "f"] & e_2 \arrow[dr, dash, "f"] & e_2 \\
e_3 & e_3 & e_3
\end{tikzcd}$$

This is the subspace of $\mathbb{K}^3 \times \mathbb{K}^3$ generated by $\mathbb{K}\{(e_1, e_3)\}$. As another example, let f and g be as before. Then we may view the relation $g \cdot f \cdot f$ as,

$$\begin{tikzcd}
e_1 \arrow[dr, dash, "f"] & e_1 & e_1 & e_1 \\
e_2 \arrow[dr, dash, "f"] & e_2 \arrow[dr, dash, "f"] & e_2 & e_2 \\
e_3 & e_3 & e_3 \arrow[ur, dash, "g"] & e_3
\end{tikzcd}$$

This is the subspace generated by $\mathbb{K}\{(e_1, e_2)\}$. For any relation C on V, define the **stable kernel of** C^{-1}, to be $\kappa(C) = \bigcup_{n \geq 0} C^n 0_V$. Define the **stable image of** C, to be $\iota(C) = \bigcap_{n \geq 0} C^n V$. As an example, let us return to our endomorphisms f and g and the following visualizations,

$$\begin{tikzcd}
e_1 \arrow[dr, dash, "f"] & e_1 & e_1 & \boxed{e_1} \\
e_2 \arrow[dr, dash, "f"] & e_2 \arrow[dr, dash, "f"] & e_2 & \boxed{e_2} \\
e_3 & e_3 & e_3 & \boxed{e_3}
\end{tikzcd}, \qquad
\begin{tikzcd}
e_1 & e_1 & e_1 & \boxed{e_1} \\
e_2 \arrow[ur, dash, "g"] & e_2 \arrow[ur, dash, "g"] & e_2 & \boxed{e_2} \\
e_3 \arrow[ur, dash, "g"] & e_3 & e_3 & \boxed{e_3}
\end{tikzcd}$$

Relation	Stable Spaces
$\kappa(f)$	$\mathbb{K}\{(e_1, e_2), (e_2, e_3), (e_1, e_3)\}$
$\iota(f)$	0
$\kappa(g)$	$\mathbb{K}\{(e_2, e_1), (e_3, e_2), (e_3, e_1)\}$
$\iota(g)$	0
$\kappa(gf)$	$\mathbb{K}\{(e_1, 0)\}$
$\iota(gf)$	$\mathbb{K}\{(e_1, e_1), (e_2, e_2)\}$
$\kappa(fg)$	$\mathbb{K}\{(e_3, 0)\}$
$\iota(fg)$	$\mathbb{K}\{(e_2, e_2), (e_3, e_3)\}$

TABLE 1. Stable kernels of $f^{-1}, g^{-1}, (fg)^{-1}$, and $(gf)^{-1}$; and stable images of f, g, fg, and gf.

$$
\begin{tikzcd}

\end{tikzcd}
$$

1.2. Properties of Relations. Suppose we have a relation on V identified with an endomorphism $f : V \to V$. Then there are subspaces $U_1, U_2 \subset V$, such that

(1) $V = U_1 \oplus U_2$,
(2) $f = (f \cap (U_1 \times U_1)) \oplus (f \cap (U_2 \times U_2))$,
(3) $f \cap (U_1 \times U_1)$ is the graph of an automorphism $f|_{U_1}$,
(4) $\kappa(f) \oplus U_1 = \iota(f)$,
(5) f induces an automorphism φ on $\iota(f)/\kappa(f)$ such that $\varphi(x + \kappa(f)) = (fx \cap \iota(f)) + \kappa(f)$, for all $x \in \iota(f)$,
(6) the relation ϕ on $\iota(f)/\kappa(f)$ is the **regular part** of f, and splits off.

2. Words on the Quiver

A **word** on the quiver Q is a finite sequence of arrows and their formal inverses:

$$w = a_1^{\epsilon_1} a_2^{\epsilon_2} \cdots a_n^{\epsilon_n}, \quad a_i \in Q_1, \quad \epsilon_i \in \{\pm 1\}.$$

The alphabet for these words is $Q_1 \cup Q_1^{-1}$, where Q_1^{-1} denotes the formal inverses of arrows. A word is reduced if no arrow is immediately followed by its inverse. For a gentle algebra with zero-relations, words satisfying all the zero-relations—i.e., avoiding the forbidden length-2 concatenations—constitute the combinatorial data that indexes indecomposable representations. In particular, modulo the gentle relations, words and their equivalence classes provide a complete classification of the indecomposable modules over the algebra.

3. Strings

A **string** is a reduced word $w = a_1^{\epsilon_1} a_2^{\epsilon_2} \cdots a_n^{\epsilon_n}$ on the quiver that avoids all zero-relations. Each string w corresponds to a unique indecomposable **string module** $M(w)$. The module structure is defined by assigning vector spaces to each vertex: if v is a vertex, then $\dim M(w)|_v$ equals the number of times v appears in the walk traced by w through the quiver. The dimension vector of $M(w)$ is precisely this tuple of visit counts. String modules are indecomposable and rigid, and distinct strings yield non-isomorphic modules. The collection of all string modules of a gentle algebra provides a large class of indecomposable representations, often comprising the entire indecomposable class for algebras of finite representation type.

4. Bands

A **band** is a cyclic string $b = a_1^{\epsilon_1} a_2^{\epsilon_2} \cdots a_m^{\epsilon_m}$ that is primitive, meaning it is not a proper power of a shorter cyclic word. Each band b gives rise to a continuous family of indecomposable **band modules** $M(b, \lambda, n)$ parametrized by:

(1) the band b itself,

(2) a scalar $\lambda \in k^* \setminus \{1\}$ (the deformation parameter), and

(3) a positive integer $n \in \mathbb{Z}_{>0}$ (the Jordan block size).

Band modules are the representation-theoretic source of periodic behavior and continuous families in the module category. For a fixed band and Jordan size, varying λ over k^* produces a family of non-isomorphic indecomposable modules. This continuous parametrization is the algebraic origin of the "cyclic time" or "clock periodicity" that underlies the rest of this work.

5. The Functorial Filtration

Suppose we have some index set I, and Q and $\mathcal{Q}_i$, $i \in I$ abelian categories[7]. Suppose $S_i : \mathcal{Q}_i \to Q$ and $F_i : Q \to \mathcal{Q}_i$ are additive functors[8]. Suppose further that[9]

(1) $F_i S_i \cong \mathrm{id}_{\mathcal{Q}_i}$.

(2) $F_i S_j \cong 0$ if $i \neq j$.

(3) The set $\{F_i : i \in I\}$ is **locally finite**, and **reflects isomorphisms**.

[7]Recall: an abelian category can be thought of as the path category of a quiver Q, such that we have addition on Q_0 (vertices) and also on Q_1 (arrows). In particular, Q_0, and $Q(x, y)$ are abelian groups.

[8]Identifying quivers with categories, an additive functor can be thought of as a quiver map (directed graph map) $\theta : Q \to Q'$, so that there is an additive structure on the maps $x \to \theta(x)$, $x \in Q_0$, $\theta(x) \in Q'_0$.

[9]We say the functor (quiver map) $F_i : Q \to \mathcal{Q}_i$ is **locally finite** if only finitely many $F_i(x) \in \mathcal{Q}_{i,0}$ are nonzero, for $x \in Q_0$. We say it **reflects isomorphisms** if $F_i(a) \in \mathcal{Q}_i(F_i(x), F_i(y))$ is an isomorphism for all $i \in I$, then $a \in Q(x, y)$ is an isomorphism. Here of course $x = ta$ and $y = ha$.

(4) For every $M \in \mathcal{M}$, and $i \in I$, there is a map $\gamma_{i,M} : S_i F_i(M) \to M$ such that $F_i(\gamma_{i,M})$ is an isomorphism.

How should one think of such a definition? What is a "good" picture to have in mind? First observe the following diagrams,

$$\begin{tikzcd} x' \in Q_{i,0} \arrow[rr, "Grid_{Q_i}"] \arrow[dr, "S_i"'] & & x' \in Q_i \\ & S_i(x') \in Q_0 \arrow[ur, "F_i"'] & \end{tikzcd}$$

$$\begin{tikzcd} & F_i(x) \in Q_{i,0} \arrow[dr, "S_i"] & \\ x \in Q_0 \arrow[ur, "F_i"] \arrow[rr, "\gamma_{i,x}"'] & & S_i F_i(x) \in Q_0 \end{tikzcd}$$

If all of the above properties are satisfied, then the **indecomposable objects** in Q are all of the form $S_i(m)$, with m an indecomposable objects in Q_i. All objects of the form $S_i(m)$ are indecomposable. Moreover, $S_i(V) \cong S_j(V')$ if and only if $i = j$ and $V \cong V'$ in Q_i. Now, framing this in terms of *representations* V in $Grrep(\Lambda_i) = Q_i$[10], and idenitifying the category $Grrep(\Lambda_i)$ of representations of the quiver (or quiver with relations) Λ_i, with the quiver Q_i, the above construction says we have the following diagrams of categories of representations,

$$\begin{tikzcd} & F_i(V) \in Grrep(\Lambda_i) \arrow[dr, "S_i"] & \\ V \in Grrep(\Lambda) \arrow[ur, "F_i"] \arrow[rr, "\gamma_{i,V}"'] & & S_i F_i(V) \in Grrep(\Lambda) \end{tikzcd}$$

6. Cantor Set Structure

The string combinatorics of a gentle surface algebra encode a Cantor-set topology. The set of all one-sided infinite strings (left-infinite reduced walks that avoid zero-relations) on the quiver may be given the product topology on the alphabet $Q_1 \cup Q_1^{-1}$. Under this topology, the space of one-sided infinite strings is homeomorphic to a Cantor set minus countably many points—the exceptional points being those strings that eventually terminate or satisfy a relation. This gives a fractal, self-similar structure to the representation-theoretic data.

6.1. Universal Cover. The **universal cover** of a gentle algebra is the path category of the universal covering quiver, obtained by unfolding all cycles in the original quiver into an infinite tree. Formally, if $\tilde{Q} \to Q$ is the universal covering map of quivers, then the path category $GrP(\tilde{Q})$ (on the infinite tree) contains all paths that lift the paths of $GrP(Q)$. Band modules of the original algebra correspond precisely to representations of $GrP(\tilde{Q})$ that are periodic under the action of the deck transformation group (fundamental group of Q). The periodicity of a band module under deck group action is exactly what realizes the algebraic notion of a "cyclic' structure: the deck group acts freely on vertices of $\tilde{Q}$, and the orbits of this action correspond to the cycles of the original quiver. A representation that is periodic with period λ along a deck transformation orbit encodes a cyclic time evolution, realizing in the representation category the discrete-to-continuous transition central to the Hilbert–Pólya program.

[10]Recall: a representation of a quiver Λ_i, denoted $V : \Lambda_i \to GrMod(k)$, is a functor which assigns vector spaces $V(x)$ to each vertex $x \in \Lambda_{i,0}$, and linear maps $V(a)$ to each arrow $a \in \Lambda_{i,1}$.

CHAPTER 5

DG and A_∞ foundations: making "derived time" honest

The main body introduces DG-algebras to motivate multiparameter persistence and derived invariants (Chapter 4). Here we expand the DG/A_∞ layer in the direction needed for two goals:

(1) a mathematically sound interface between surface orders and persistence computations, and

(2) an operator-theoretic interface between "clock shifts" and Hamiltonians (Hilbert–Pólya program later).

0.1. DG-algebras: conventions and minimal requirements. A differential graded (DG) algebra over a commutative ring k is a graded k-algebra $A = \bigoplus_{n\in\mathbb{Z}} A^n$ equipped with a degree +1 differential $d : A^n \to A^{n+1}$ such that

$$d^2 = 0, \qquad d(ab) = (da)b + (-1)^{|a|}a(db).$$

A DG-module over A is defined similarly; the derived category $D(A)$ is obtained by inverting quasi-isomorphisms.

Example 0.1 (A minimal example). The exterior algebra $A = \Lambda^\bullet(V)$ with $d = 0$ is a DG-algebra concentrated in non-positive degrees. A less degenerate example: let $A = k[\varepsilon]/(\varepsilon^2)$ with $|\varepsilon| = -1$ and $d\varepsilon = 1$; then $H^\bullet(A) \cong k$, so A is a "resolution" of the ground field. In our setting, A will be a DG enhancement of a surface algebra, and the differential encodes higher-order relations among paths.

Remark 0.2 (What we actually need). We do *not* need the full technology of model categories for most of this volume. We need: (i) mapping cones, (ii) derived functors (Tor/Ext), (iii) the fact that quasi-isomorphic DG-algebras have equivalent derived categories, and (iv) a controlled way to talk about "families" of DG-modules indexed by parameters.

0.2. From surface algebras/orders to DG enhancements. A surface algebra in the sense of the source text is a quiver algebra kQ/I with gentle-style relations. There are multiple DG enhancements one can attach:

(1) **Bar/cobar constructions:** produce a DG coalgebra and then a DG algebra controlling A_∞ structures.

(2) **Ginzburg DG algebras:** if a quiver with potential (Q, W) exists, one can form a 3-Calabi–Yau DG algebra $\Gamma(Q, W)$.

(3) **Geometric enhancements:** for many gentle/surface algebras, $D^b(\text{mod-}A)$ is equivalent to a (partially wrapped) Fukaya category of a marked surface; the A_∞ structure is then geometric.

We remain agnostic and formulate an *axiomatic* requirement.

Definition 0.3 (Clock-compatible DG enhancement). Let Λ be a (completed) surface order with local clock operators. A *clock-compatible DG enhancement* of Λ is a DG algebra A together with:

- a quasi-isomorphism $H^0(A) \simeq \Lambda$,
- a distinguished degree-0 element (or automorphism) $T \in Z^0(A)$ representing the clock shift in cohomology,
- functoriality with respect to gluing: gluing of orders induces DG-algebra maps up to homotopy.

The point of this definition is not to impose an arbitrary DG gadget; it is to make sure that "clock data" survives passage to derived categories and hence can interact with persistence constructions.

0.3. The minimal A_∞ model viewpoint. Even when A is concentrated in degree 0 (an ordinary algebra), the derived category remembers higher multiplications via A_∞ minimal models. The cleanest formulation for computations is:

THEOREM 0.4 (Kadeishvili (minimal model)). *Let A be a DG algebra over a field. Then its cohomology $H^*(A)$ admits an A_∞ algebra structure $(m_2, m_3, \dots)$ such that:*

- *m_2 is the induced product on cohomology,*
- *there exists an A_∞ quasi-isomorphism $H^*(A) \to A$,*
- *the A_∞ structure is unique up to A_∞ quasi-isomorphism.*

REMARK 0.5 (Why m_3 matters for time/geometry). The first genuinely new datum beyond associative multiplication is m_3. Physically, m_3 is a measure of nontrivial associator/phase information in composing local processes. Mathematically, m_3 detects Massey products and obstructions to formality. In emergent-geometry language, it is the first place where "curvature" can appear in a purely algebraic composition law.

0.4. Realistic example: the double 3–cycle algebra and its Ext-A_∞. Let A be the path algebra of the double 3–cycle quiver from Section 4, modulo gentle relations (4.1)–(4.2). Even in this toy case, one can see the distinction between:

- the *presentation* by generators/relations, and
- the *derived* composition data encoded by higher operations in $\mathrm{Ext}^*_A(S, S)$ for simples S.

PROPOSITION 0.6 (Ext algebra skeleton (informal)). *For a simple A-module S supported at a medial vertex, $\mathrm{Ext}^1_A(S, S)$ is spanned by (classes of) the two local directions (clockwise/counterclockwise arrows), while $\mathrm{Ext}^2_A(S, S)$ detects the first forbidden length-2 turns. Higher* Ext *groups are controlled by periodicity of walks on the quiver.*

REMARK 0.7. This is the derived-category version of the combinatorial statement "there are two arrows in and two arrows out" in a surface algebra (see the source text in Appendix A).

A concrete computational pipeline (Macaulay2 or Sage) is provided in Section 6 for related persistence modules. For DG/A_∞ computations, one typically proceeds by choosing a projective resolution $P^\bullet \to S$ and forming the DG endomorphism algebra $\mathrm{End}(P^\bullet)$; its cohomology carries the desired A_∞ structure.

0.5. Derived invariants that behave like conserved quantities. A central promise in the open-problems list is to compute derived invariants (Hochschild (co)homology, Calabi–Yau structures) of clocked surface DG-algebras and interpret them physically (§13.2.1).

We record the minimal dictionary.

DEFINITION 0.8 (Hochschild homology and cohomology). For a DG algebra A, Hochschild homology is

$$HH_*(A) = \mathrm{Tor}^{A^e}_*(A, A), \qquad A^e = A \otimes_k A^{op},$$

and Hochschild cohomology is

$$HH^*(A) = \mathrm{Ext}^*_{A^e}(A, A).$$

REMARK 0.9 (Physical reading). In many QFT and string-theoretic contexts, Hochschild cohomology controls deformations of the algebra of observables, while Hochschild homology controls "closed-string" or "trace" sectors. Within the present program, the robust claim is:

Clock holonomy constraints are deformation constraints, hence should appear as classes in $HH^*(A)$ or as obstructions detected by them.

0.6. Hamiltonians from shifts: the logarithm trick. The main body already sketches how a shift operator can be viewed as a discrete-time evolution $T = e^{-iH\Delta t/\hbar}$ (§6.6; see also the discussion around diagonalizing T on a finite d–qudit).

The mathematically correct statement is:

Proposition 0.10 (From a unitary shift to a self-adjoint generator). *Let T be a unitary on a Hilbert space $\mathcal{H}$. Then by functional calculus there exists a self-adjoint operator H (not unique) such that*

$$T = e^{-iH}.$$

If we specify a time step Δt and Planck's constant $\hbar$, we may write $T = e^{-iH\Delta t/\hbar}$ after rescaling.

Remark 0.11 (Nonuniqueness and branch choices). The logarithm of a unitary is multi-valued; choosing H requires choosing a branch cut for the eigenphases. In the Hilbert–Pólya program we exploit this nonuniqueness as a feature: branch choices correspond to arithmetic/holonomy constraints that must be fixed by additional structure (trace formulas, positivity, or spectral symmetries).

For nonunitary truncations (nilpotent/unipotent), the generator is not self-adjoint and must be implemented on hardware by dilation (§12.3). We expand the engineering consequences in Section 23.

0.7. DG flows and multiparameter filtrations. To connect DG algebra to multiparameter persistence we need a mechanism that produces *families* of complexes. The clean algebraic model is:

Definition 0.12 (Multiparameter filtered DG module). Let $(\P, \leq)$ be a poset (e.g. $\mathbb{N}^n$). A $\P$*–filtered DG A-module* is a family $\{M_p\}_{p\in\P}$ of DG modules together with structure maps $M_p \to M_q$ for $p \leq q$ such that:

(1) each map is a DG-module map,
(2) compositions are strictly associative (or associative up to specified homotopies in a higher-categorical refinement).

In practice, $\P = \mathbb{N}^2$ is the first nontrivial case: one parameter is a geometric/scale parameter, the other is an information/entanglement threshold. Section 6 turns this into explicit computations.

CHAPTER 6

Explicit multiparameter persistence computations tied to surface orders

This chapter is the computational core of the extended edition. It expands the bridge chapter (Chapter 4) by giving:

(1) an explicit *bifiltration* naturally attached to clocked surface orders and entanglement data,
(2) a concrete translation to bigraded modules over polynomial rings (the commutative-algebra model),
(3) worked toy computations (including Macaulay2 templates),
(4) and a pipeline intended to be implementable on realistic quantum hardware outputs.

0.1. From a surface order to a bifiltration. The core idea is to convert entanglement data on the surface into a two-parameter family of simplicial complexes, where one parameter controls *spatial scale* (how far we look on the graph) and the other controls *correlation strength* (how entangled a pair must be to count as connected). This is the minimal construction that keeps geometric and information-theoretic data logically separated, and it is what makes multiparameter persistence the natural tool rather than a decorative upgrade.

Let $\Gamma \subset \Sigma$ be an embedded graph underlying a surface algebra/order, and attach to each vertex v a local Hilbert space $\mathcal{H}_v$ and local clock operator S_v (possibly twisted, Section 2). Fix a global state $|\psi\rangle \in \bigotimes_{v\in V(\Gamma)} \mathcal{H}_v$.

We construct a *two-parameter filtration* indexed by

$$(r, \lambda) \in \mathbb{R}_{\geq 0} \times \mathbb{R}_{\geq 0},$$

where:

- r is a *geometric/graph* scale (how far we look on Γ),
- λ is an *information threshold* (how strong correlations must be to count as "present").

0.1.1. *Raw data: a weighted correlation graph.* From $|\psi\rangle$ define a symmetric weight matrix $W_\psi(u, v)$. A standard choice is mutual information

$$W_\psi(u, v) = I(u : v) = S(u) + S(v) - S(uv),$$

or a Rényi proxy I_2 when only randomized measurements are available (§12.6).

Definition 0.1 (Thresholded correlation graph). For $\lambda \geq 0$, define the thresholded graph Γ_λ on the same vertex set by including an edge (u, v) if $W_\psi(u, v) \geq \lambda$.

0.1.2. *Geometric thickening: Vietoris–Rips on a graph metric.* Let d_{comb} be the shortest-path metric on the 1–skeleton of Γ (unit edge lengths, or weighted by geometric data when available). For $r \geq 0$, define the r–ball neighborhoods and construct a simplicial complex.

Definition 0.2 (Bifiltered complex). Let $K_{r,\lambda}$ be the Vietoris–Rips complex on the vertex set $V(\Gamma)$, using the metric d_{comb}, but with the additional constraint that simplices are only allowed if all their edges lie in Γ_λ. Equivalently, $K_{r,\lambda}$ is generated by cliques in Γ_λ of diameter $\leq r$.

Then $(r, \lambda) \leq (r', \lambda')$ (meaning $r \leq r'$ and $\lambda \geq \lambda'$ if we view λ as a threshold) induces an inclusion

$$K_{r,\lambda} \hookrightarrow K_{r',\lambda'}.$$

Remark 0.3 (Monotonicity conventions). There are two common conventions:

- treat both parameters as increasing (larger means "more included"),
- or treat one as a decreasing threshold. We will always explicitly state the poset used; the algebraic model uses $\mathbb{N}^2$ with coordinatewise order.

0.2. Persistence modules as bigraded modules over $k[x, y]$. Fix a homology degree k. Define

$$M_{r,\lambda} := H_k(K_{r,\lambda}; k),$$

with structure maps induced by inclusions.

Discretize parameters to a grid (r_i, λ_j) and index by $\mathbb{N}^2$:

$$M_{(i,j)} := M_{r_i,\lambda_j}.$$

Then M becomes an $\mathbb{N}^2$-graded persistence module. As recalled in the source text (Appendix B in the volume), such modules can be modeled as modules over a polynomial ring.

Definition 0.4 (Bigraded module model). Let $R = k[x, y]$ with $\deg x = (1, 0)$ and $\deg y = (0, 1)$. An $\mathbb{N}^2$-graded persistence module with structure maps corresponding to increments in i and j is equivalent (under mild finiteness hypotheses) to a finitely generated $\mathbb{N}^2$-graded R-module.

The equivalence is realized by letting x act by the map $M_{(i,j)} \to M_{(i+1,j)}$ and y act by $M_{(i,j)} \to M_{(i,j+1)}$. This is the commutative-algebra "engine" that powers generic free resolutions, determinantal varieties, and stability criteria (Appendix B).

0.3. What to compute: rank invariants, Betti tables, and jump loci. For one-parameter persistence, barcodes are complete invariants over a field. For two parameters, no such complete discrete invariant exists. However, several computable invariants are both meaningful and stable.

0.3.1. *Rank invariant.* For $p \leq q$ in the poset, let $\varphi_{p,q} : M_p \to M_q$ be the structure map.

Definition 0.5 (Rank invariant). The rank invariant is

$$\rho(p, q) := \operatorname{rank}(\varphi_{p,q}).$$

Geometrically, fixing p, q and bounding the rank corresponds to determinantal varieties (Appendix B); computationally, ρ is often the first robust summary one can estimate from noisy data.

0.3.2. *Free resolutions and Betti numbers.* A finitely generated bigraded R-module has a minimal free resolution

$$\cdots \to \bigoplus R(-\alpha)^{\beta_{2,\alpha}} \to \bigoplus R(-\alpha)^{\beta_{1,\alpha}} \to \bigoplus R(-\alpha)^{\beta_{0,\alpha}} \to M \to 0,$$

where $\alpha \in \mathbb{N}^2$ and $\beta_{i,\alpha}$ are bigraded Betti numbers.

Remark 0.6 (Why Betti tables matter here). In this program, the Betti data is not just "commutative algebra for its own sake": Betti numbers detect *how many independent topological features* are created and destroyed in each parameter direction, and the degrees tell you *where* in the (r, λ) plane those events concentrate.

0.4. Toy computation 1: a four-vertex surface-order patch. Consider a small patch of a triangulated surface consisting of four vertices forming two triangles sharing an edge. Let the vertices be $1, 2, 3, 4$ with edges $(1, 2), (2, 3), (1, 3)$ and $(2, 3), (2, 4), (3, 4)$.

Assume we have measured (or simulated) correlation weights $W_\psi(u, v)$ on these edges. We pick two thresholds $\lambda_0 > \lambda_1$ and two radii $r_0 < r_1$ such that:

- at (r_0, λ_0) we have only the single shared edge $(2, 3)$;
- at (r_0, λ_1) we have a triangle $(1, 2, 3)$;
- at (r_1, λ_1) we have both triangles, hence a contractible complex.

Then $H_1(K_{r,\lambda})$ is nontrivial only at intermediate parameters: the triangle at (r_0, λ_1) creates a 1-cycle in the 1–skeleton that is immediately filled by the 2-simplex, so the persistent H_1 is trivial; but H_0 has a nontrivial merging event.

This toy is boring topologically, but it is useful algebraically because it yields a small presentation matrix.

0.4.1. *Module presentation.* Let M be the H_0 persistence module. On a 2×2 grid, M is presented by generators corresponding to connected components and relations corresponding to mergers.

The point is not that this exact matrix encodes the geometric toy perfectly; the point is that *the entire pipeline* from filtration to module to resolution can be scripted in Macaulay2.

0.5. Toy computation 2: persistence from clock holonomy constraints. Now we build a toy where the algebraic "clock constraint" is genuinely present.

Let Γ be a cycle graph of length m (a single face boundary). Attach to each vertex a clock generator S_v, and impose a holonomy constraint that the product around the cycle equals a central element:

$$S_{v_1} S_{v_2} \cdots S_{v_m} = \pi^k I. \tag{0.1}$$

Interpret (0.1) as a *family* of constraints indexed by two parameters:

- a correlation threshold λ controlling which edges of the cycle are "active",
- a scale r controlling whether the cycle is detected (needs all edges).

Then the appearance/disappearance of the cycle in $K_{r,\lambda}$ correlates with satisfaction/violation of the holonomy constraint. This motivates a computational observable:

$$\Delta(r, \lambda) := \left\| S_{v_1} \cdots S_{v_m} - \pi^k I \right\|$$

(for an operator norm or spectral distance), treated as a function on parameter space. Taking sublevel sets $\{\Delta \leq \epsilon\}$ yields an additional filtration direction; one can study a 3-parameter module in principle, but in practice one compresses by fixing ϵ and studying the induced 2-parameter persistence.

Remark 0.7 (Why this is not vacuous). If S_v are pure permutation shifts, the product around a cycle is often exactly identity (up to conjugacy), so Δ carries little information. If S_v are twisted shifts $S_m(\pi)$, the product accumulates valuation factors; Δ becomes sensitive to gluing and to local ramification—exactly the "time dilation" lever.

0.6. Stability: what multiparameter persistence can guarantee. The empirical pipeline (Section 23) produces noisy estimates of $W_\psi(u, v)$. Therefore, any topological summary must be stable under perturbations.

One robust statement is:

Proposition 0.8 (Stability of rank invariants (informal)). *If two bifiltered complexes $(K_{r,\lambda})$ and $(K'_{r,\lambda})$ are ε–interleaved (with respect to an appropriate metric on the parameter plane), then their rank invariants differ by at most ε in the induced parameter distortion.*

This is the correct multiparameter substitute for barcode stability. The generic-free-resolution technology in Appendix B (Buchsbaum–Eisenbud style) is particularly useful because it identifies *which algebraic features are stable and which are intrinsically unstable* (jump loci of determinantal varieties).

0.7. Pipeline: from 10k-qubit hardware logs to persistence invariants. We now state an end-to-end pipeline in implementation form. Inputs are assumed to come from quantum hardware experiments as described in Section 23.

Input.

- A hardware connectivity graph G_{hw} with $N \sim 10^4$ qubits.
- A chosen embedded graph model $\Gamma \subset \Sigma$ (logical graph) and a mapping of Γ into G_{hw} via SWAP networks if needed.
- A family of circuits $U(\lambda)$ producing states $|\psi(\lambda)\rangle$, and measurement logs sufficient to estimate $W_\psi(u, v)$ on edges (at least for neighboring vertices in Γ).

Steps.

(1) **Estimate correlation weights.** Produce $W_\psi(u, v)$ (mutual information or proxy) with error bars.
(2) **Choose parameter grid.** Select radii r_i and thresholds λ_j based on quantiles of W_ψ and graph diameters.
(3) **Build bifiltered complexes.** For each (i, j) compute K_{r_i,λ_j} (using clique enumeration on sparse graphs; for large N restrict simplex dimension).
(4) **Compute homology.** Compute $H_k(K_{r_i,\lambda_j})$ for small k (typically $k = 0, 1, 2$) using sparse boundary matrices.
(5) **Assemble module.** Create the bigraded module M by storing vector spaces and maps.
(6) **Compute invariants.** Compute rank invariant ρ for selected pairs (p, q) and/or compute a free resolution and Betti numbers on smaller induced submodules (windows) using Macaulay2.
(7) **Validate stability.** Perturb weights within error bars (bootstrap) and recompute invariants; stable invariants are candidates for physical interpretation.

Validation checks and failure modes.

- If W_ψ is too noisy, thresholding produces spurious topological changes; mitigate via averaging and restricting to local neighborhoods.
- Clique complexes blow up combinatorially; mitigate by bounding simplex dimension (e.g. only up to triangles) and using witness complexes.
- Two-parameter resolutions are expensive; use windowed computations and rank invariants as primary summaries.

0.8. Where the surface-order structure enters computationally. The filtration above only used the embedded graph and entanglement weights. Surface orders contribute additional structure that can be injected in two ways:

(1) **Local degrees / valences.** Vertex order sizes m_v determine the local clock dimension and hence the plausible correlation structure (e.g. higher valence $\Rightarrow$ more local degrees of freedom).
(2) **Valuations and twisted shifts.** Local uniformizers π_v (or effective parameters derived from entanglement) modify the clock generators S_v; holonomy constraints then define an *algebraic energy landscape* whose sublevel sets yield alternative filtrations.

The second mechanism is the one most directly tied to emergent time and gravity: it is how information-theoretic data can influence projective holonomy spectra in a way that mimics redshift.

Part 3

Surface Orders, Twisted Shifts, and Classification

CHAPTER 7

Compact Gentle Surface Orders

1. Orders and Burban-Drozd Gluing

1.1. Definitions and Properties.

Definition 1.1. Let R be a complete noetherian local domain with field of fractions $\mathbb{K}$, and residue field k. An R-**Order** Λ in a k-algebra A is a unital subring of A such that

(1) $\mathbb{K}\Lambda = A$, and

(2) Λ is finitely generated as an R-module.

Let $C = [\sigma, \alpha, \phi]$ be a constellation, and let $\Gamma \hookrightarrow \Sigma$ be the associated graph cellularly embedded in the closed Riemann surface Σ. Further, let $n(i) = n_i$ denote the length of the cycle given by σ_i[1]

(1) For each cycle $\sigma_i \in \Gamma_0$ associated to the vertex i, we associate a local order $\Omega_i = \Omega(\sigma_i)$, and a regular principal ideal $\omega_i := \omega_0(\sigma_i)\Omega_i = \Omega_i\omega_0(\sigma_i)$.

(2) The **hereditary**[2] order associated to σ_i is then given by

$$\mathbb{H}_i = \begin{pmatrix} \Omega_i & \omega_i & \omega_i & \cdots & \omega_i & \omega_i \\ \Omega_i & \Omega_i & \omega_i & \cdots & \omega_i & \omega_i \\ \Omega_i & \Omega_i & \Omega_i & \cdots & \omega_i & \omega_i \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ \Omega_i & \Omega_i & \Omega_i & \cdots & \Omega_i & \omega_i \\ \Omega_i & \Omega_i & \Omega_i & \cdots & \Omega_i & \Omega_i \end{pmatrix}_{n(i)}$$

(3) Let $\Omega_i^{(k,k)}$ denote the (k, k) entry of Ω_i in $\mathbb{H}_i$.

(4) For each $1 \leq k \leq n_i$ let

$$P_{i,k} := \begin{pmatrix} \omega_i \\ \vdots \\ \omega_i \\ \Omega_i \\ \Omega_i \\ \vdots \\ \Omega_i \\ \Omega_i \end{pmatrix}$$

where the first entry equal to Ω_i is the kth row.

[1]Recall: for a constellation $C = [\sigma, \alpha, \phi]$ and the associated graph Γ on a (compact) closed Riemann surface Σ, the length of the (nonzero) cycle in the gentle medial quiver $Q(C)$, associated to σ_i is just the order of the cycle σ_i. Here we are using the notation $\sigma = \sigma_1\sigma_2 \cdots \sigma_r$, where $\sigma_i \in S_{[2m]}$ is a cycle permutation.

[2]An algebra, or an order, is hereditary if no module has a minimal projective resolution greater than length 1. This means the *projective dimension* of any module is no greater than 1, and therefore the global dimension is at most 1.

The modules $\{P_{i,k} : 1 \leq k \leq n_i\}$ give a complete set of non-isomorphic indecomposable projective $\mathbb{H}_i$-modules, with the natural inclusions

$$P_{i,1} \hookleftarrow P_{i,2} \hookleftarrow \cdots \hookleftarrow P_{i,n_i-1} \hookleftarrow P_{i,n_i} \hookleftarrow P_{i,1}.$$

where the final map is given by left-multiplication by $\omega_0(\sigma_i)$. If we identify $P_{i,k}$ with the edge $e^i_k = e_k(\sigma_i)$, where $\sigma_i = (e^i_1, e^i_2, ..., e^i_{n_i})$ is a cyclic permutation, then the chain of inclusions can be interpreted in terms of the cycle σ_i. From the embedding $\Gamma \hookrightarrow \Sigma$ given by the constellation $C = [\sigma, \alpha, \phi]$, this can be interpreted as walking clockwise around the vertex of σ_i. We will take $P_{i,k} = P_{i,k+n_i}$, but each e^i_k must be multiplied by the automorphism σ_i after one trip around the cycle, i.e. there is some multiplication by a power of $\omega_0(\sigma_i)$ involved. In particular, conjugation by

$$\underline{\omega}_i := \begin{pmatrix} 0 & 0 & 0\cdots & 0 & \omega_0(\sigma_i) \\ 1 & 0 & 0\cdots & 0 & 0 \\ 0 & 1 & 0\cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0\cdots & 0 & 0 \\ 0 & 0 & 0\cdots & 1 & 0 \end{pmatrix}_{n_i}$$

2. Local vertex orders and the π–twisted shift

The main body already identifies the *pure* cyclic successor at a valence-m vertex with the permutation matrix T_v (§3.4.1). However, in a local *order*—especially a hereditary order over a discrete valuation ring—the natural successor that normalizes the order often picks up a uniformizer factor on the wrap-around step. This is precisely the twisted shift we now define:

$$S_3(\pi) = \begin{pmatrix} 0 & 0 & \pi \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

2.1. Set-up: hereditary order over a DVR. Let $(R, \mathfrak{m})$ be a discrete valuation ring with uniformizer π and fraction field K. The standard (Iwahori-type) hereditary order of type m is

$$\Lambda_m(R) = \begin{pmatrix} R & R & \cdots & R \\ \pi R & R & \cdots & R \\ \vdots & \vdots & \ddots & \vdots \\ \pi R & \pi R & \cdots & R \end{pmatrix} \subset \mathrm{Mat}_m(K). \tag{2.1}$$

This is the local model appearing (in slightly different notation) in the source text in Appendix A, and it is also the canonical "vertex order" for a cycle of length m in a dessin order.

2.2. The twisted shift and its basic algebra.

Definition 2.1 (π–twisted successor). For $m \geq 2$, define the π–twisted shift (companion) matrix

$$S_m(\pi) = \begin{pmatrix} 0 & 0 & \cdots & 0 & \pi \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix} \in \mathrm{Mat}_m(K). \tag{2.2}$$

Lemma 2.2 (Order-compatibility). *$S_m(\pi)$ normalizes the hereditary order $\Lambda_m(R)$ in the sense that*

$$S_m(\pi)\, \Lambda_m(R)\, S_m(\pi)^{-1} = \Lambda_m(R).$$

In particular, conjugation by $S_m(\pi)$ is an automorphism of the local order and is therefore an "allowed" symmetry (a clock move) in the operator-algebra interpretation.

Proof. A direct computation using the valuation filtration on matrix entries is easiest. Conjugation by the pure permutation matrix cyclically permutes the standard lattice chain

$$R^m \supset \mathfrak{m} \oplus R^{m-1} \supset \mathfrak{m}^2 \oplus \mathfrak{m} \oplus R^{m-2} \supset \cdots$$

that defines $\Lambda_m(R)$ as its endomorphism ring. The π in the $(1, m)$ entry exactly compensates the valuation jump on the wrap-around step so that the lattice chain is preserved rather than shifted out of phase. Equivalently, one checks on matrix units E_{ij} that valuations transform compatibly: the entries that must lie in πR remain in πR after conjugation. □

Proposition 2.3 (Central power relation). *The twisted shift satisfies*

$$S_m(\pi)^m = \pi\, I_m.$$

Consequently, in the projective linear group $\mathrm{PGL}_m(K)$ *the class of* $S_m(\pi)$ *has* finite order *dividing* m.

Proof. Apply $S_m(\pi)$ to the standard basis vectors $e_1, \ldots, e_m$: $Se_i = e_{i+1}$ for $i < m$ and $Se_m = \pi e_1$. Iterating m times maps each basis vector to π times itself, hence $S^m = \pi I$. □

Remark 2.4 (Why this matters for time holonomy). The discussion of cyclic time (as torsion holonomy) becomes more rigid in the presence of Proposition 2.3: even if $S_m(\pi)$ has infinite order in $\mathrm{GL}_m(K)$ (because π is not a root of unity), its projective class is torsion. This is the algebraic shadow of a geometric fact: local time may be "non-compact" (a $\mathbb{Z}$–cover), while global time is cyclic up to a central scaling that is invisible to projective measurements.

2.3. Spectral geometry viewpoint. If $K = \mathbb{C}((t))$ and $\pi = t$, the eigenvalues of $S_m(t)$ are the roots of $x^m - t = 0$, i.e. $t^{1/m}\zeta_m^j$. Thus the twisted shift is a discrete model of a clock with a tunable "rate" set by the valuation of π. Later chapters will exploit this to connect:

$$\text{entanglement density} \longrightarrow \text{effective valuation data} \longrightarrow \text{clock redshift.}$$

3. How the corrigendum and twisted shift plug into the main narrative

Two themes introduced here reappear everywhere:

(1) **Orientation and time.** The double-3–cycle on the sphere makes the time-orientation choice algebraic, not rhetorical: two opposite cycles correspond to two local time directions, and relations determine whether and how one can switch.

(2) **Ramification and clock drift.** The factor π in $S_m(\pi)$ is the minimal local datum that can create global drift/holonomy effects when orders are glued. In Chapter 18 we make this precise by describing gluing as a cocycle valued in normalizers of local orders.

3.1. Vertex-cycle moves, forbidden face cycles, and reversal by switching to an adjacent vertex cycle. The phrase "choose an orientation and walk around the vertex cycle" hides a subtlety that becomes important once we insist that *only certain cycles survive in the quotient by the gentle ideal*. Because the Hilbert–Pólya/GRH section uses these cycles as *clock* degrees of freedom, we spell out the combinatorics carefully.

3.1.1. *Dessin permutations versus quiver relations.* For a bipartite dessin (or, equivalently, the monodromy of a Belyi map) we have a permutation triple

$$(\sigma_0, \sigma_1, \sigma_\infty) \in S_D^3, \qquad \sigma_0\sigma_1\sigma_\infty = 1,$$

acting on the dart set D (oriented half-edges). Cycles of σ_0 encode black vertices, cycles of σ_1 encode white vertices, and cycles of σ_∞ encode faces.

In the constellation notation used earlier, one often writes $C = [\sigma, \alpha, \phi]$ with α the edge-involution and $\phi = \alpha\sigma^{-1}$ the face permutation. In the special "bipartite" viewpoint of Section 0.14 we literally identify

$$(\sigma_0, \sigma_1, \sigma_\infty) = (\sigma, \alpha, \phi),$$

but for the discussion below it is enough to remember:

σ_0 and σ_1 are vertex permutations; σ_∞ is the face permutation.

Now pass to the associated gentle surface algebra (or order) $\Lambda = kQ/I$. The gentle relations are exactly the statement that, at each step, there is a unique "forbidden" continuation in the ideal I and a unique "allowed" continuation not in I. Equivalently (using the standard permutation formalism for 2–regular gentle quivers), there are two permutations on arrows:

- a successor permutation σ whose cycles are the *allowed* directed cycles ("vertex cycles" in our surface/dessin models), and
- a successor permutation ϕ whose cycles are the *anti-cycles* (cycles of zero relations), i.e. the compositions along these cycles land in I.

In the bipartite dessin setting, the allowed cycles are precisely the vertex cycles coming from σ_0 and σ_1, whereas the face cycles coming from σ_∞ are the anti-cycles:

walking around a σ_0- or σ_1-vertex is allowed (not in I), while attempting to walk around a σ_∞-face is killed by the ideal.

3.1.2. *What "reversal" means algebraically: inverse arrows and forced switching.* A directed walk in the quiver uses arrows in their orientation. To model a geometric walk that sometimes goes *against* the arrow orientation (e.g. reversing direction along a cycle), one uses the standard string-algebra convention: for each arrow a one introduces a formal inverse symbol a^{-1}, interpreted as traversing the same geometric edge in the opposite direction.

In a gentle quiver, a "string" is a word in arrows and inverse arrows with two constraints: (i) no immediate cancellation aa^{-1} or $a^{-1}a$, and (ii) no forbidden subword whose corresponding length-2 path lies in the ideal I. Because every vertex has out-degree 2, these constraints have a striking consequence:

*If you traverse an arrow a and then reverse (use a^{-1}), the next step is forced: you must exit along the **other** outgoing arrow at that vertex, hence you jump to the **adjacent** vertex cycle.*

In the dessin language, this is exactly the reversal move described above: starting from an allowed vertex cycle (coming from σ_0 or σ_1), a reversal against the quiver arrows forces you onto the adjacent allowed cycle at the same edge (the other endpoint of that edge), rather than allowing you to continue around a face. The forbidden alternative would be to follow the face permutation σ_∞, but that continuation is precisely what the ideal I forbids.

3.1.3. *Translation into clock operators: forward shifts, backward shifts, and "different shifts".* Fix a vertex v of valence m_v carrying a DVR (R_v, π_v) and ramification exponent e_v. On the corresponding local projective chain (or, in the quantum model, on the local Hilbert space with basis $\{|1\rangle, \dots, |m_v\rangle\}$) the forward cyclic motion is implemented by the twisted shift

$$S_v := S_{m_v}(\pi_v^{e_v}), \qquad S_m(\pi^e) = \begin{pmatrix} 0 & 0 & \cdots & 0 & \pi^e \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix},$$

so that $S_v^{m_v} = \pi_v^{e_v} I$ and the valuation of $\pi_v^{e_v}$ measures the local "clock defect".

LEMMA 3.1 (Explicit inverse (backward shift)). *For any $m \geq 2$ and $e \geq 1$,*

$$S_m(\pi^e)^{-1} = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 & 1 \\ \pi^{-e} & 0 & \cdots & 0 & 0 \end{pmatrix}, \qquad \textit{and hence} \qquad \left(S_m(\pi^e)^{-1}\right)^m = \pi^{-e} I.$$

PROOF. On the standard basis vectors $|k\rangle$, the defining relations are

$$S_m(\pi^e)|k\rangle = |k+1\rangle \ (1 \leq k \leq m-1), \qquad S_m(\pi^e)|m\rangle = \pi^e|1\rangle.$$

The displayed matrix is the unique linear map with

$$S_m(\pi^e)^{-1}|k\rangle = |k-1\rangle \ (2 \leq k \leq m), \qquad S_m(\pi^e)^{-1}|1\rangle = \pi^{-e}|m\rangle,$$

and a direct multiplication check gives $S_m(\pi^e)\, S_m(\pi^e)^{-1} = I = S_m(\pi^e)^{-1} S_m(\pi^e)$. Raising to the mth power yields the central factor π^{-e}. □

Lemma 3.1 is the clean operator-algebraic avatar of "walking around the same vertex cycle in the opposite direction":

reversing direction replaces the forward shift S_v by the backward shift S_v^{-1}, and inverts the central defect factor.

Now incorporate the *adjacent-cycle switch*. If an edge e joins vertices v and w (in the bipartite case: a black vertex and a white vertex), then a reversal at e forces a jump from the v-cycle to the w-cycle. On the quantum side, this is implemented by the edge identification/isometry (a bimodule map in the order language)

$$U_e : \mathcal{H}_v \supset \mathcal{H}_{v\to e} \longrightarrow \mathcal{H}_{w\to e} \subset \mathcal{H}_w,$$

between the edge "corner" subspaces at e. Conjugating by U_e transports shifts across the gluing. The essential point is that *different vertices generally carry different local data* (different m, different π, different e), so an adjacent-cycle reversal is not merely S_v^{-1} but typically a **different shift operator**:

$$\text{reverse at an edge} \quad \rightsquigarrow \quad S_v^{-1} \text{ on one side } \simeq U_e^{-1}\, S_w^{\pm 1}\, U_e \text{ on the other side.}$$

This is exactly the mechanism by which a local "time reversal" move changes the valuation/holonomy bookkeeping: in the homogeneous case it flips the power of π, while in the heterogeneous case it also changes *which* uniformizer appears.

REMARK 3.2 (Why σ_∞ is singled out). In an oriented bipartite dessin one has the face-step identity $\sigma_\infty = (\sigma_0\sigma_1)^{-1} = \sigma_1\sigma_0^{-1}$ (when σ_1 is an involution, as in many toy models). Thus walking once around a face alternates a *backward* black turn (σ_0^{-1}) with a *forward* white turn (σ_1). In the gentle algebra this alternation is precisely what is killed by the ideal: face cycles are anti-cycles. The only way to realize "backward" motion without falling into the ideal is therefore to treat it as a string move (inverse arrow) and, equivalently, to switch to the adjacent vertex cycle as described above.

3.1.4. *How the adjacent-cycle reversal argument proves the claim (and why total positivity shows up).* The previous subsubsections stated the reversal rule in words. Here we make the logical implication explicit: *the gentle relations force reversal to be implemented by switching to the adjacent vertex cycle, and this forced switching is exactly what later lets us package "one tick" of evolution as a planar network (wiring diagram) with positive weights.* Both points are ultimately local.

Proposition 3.3 (Reversal forces switching to the adjacent allowed cycle). *Let $\Lambda = kQ/I$ be the gentle algebra (or order) attached to a bipartite dessin, and assume Q is 2–regular in the standard sense: at each vertex there are exactly two arrows leaving and exactly two arrows entering, and I is generated by length-2 zero relations with the gentle uniqueness property.*

Fix an arrow $a : u \to v$ of Q and consider the corresponding string *model, i.e. reduced words in arrows and formal inverses subject to (i) no immediate cancellation aa^{-1} or $a^{-1}a$, and (ii) no forbidden length-2 subword whose oriented interpretation lies in the ideal I. Suppose a string contains the letter a^{-1}, meaning that the walk traverses the underlying geometric edge in the direction* opposite *the quiver arrow.*

Then any continuation of the string past a^{-1} that remains reduced and avoids the ideal must exit the vertex u along the other outgoing arrow $b \neq a$. *In particular, the walk leaves the permitted cycle in which a occurs and enters the permitted cycle that is adjacent across the edge (the vertex cycle associated to the other endpoint of the underlying edge in the dessin).*

Proof. After traversing a^{-1} the walk is located at the tail u of a. Because the word is reduced, the next letter cannot be a (this would create the forbidden cancellation subword $a^{-1}a$). By 2–regularity there are exactly two arrows leaving u, namely a and a distinct arrow b. Hence the next arrow-oriented step must involve b (either b or b^{-1} depending on whether one continues with or against the arrow orientation).

What remains is to exclude the possibility that this continuation keeps one on the same permitted cycle. In a gentle quiver, each vertex has *exactly one* permitted continuation and *exactly one* forbidden continuation for each incoming arrow. Equivalently, the local successor permutations split the two outgoing arrows at u into:

- the arrow that continues an *allowed* (permitted) cycle, and
- the arrow that continues a *forbidden* (anti-)cycle (a length-2 path in I).

If one attempts to "reverse while staying on the same vertex cycle", the only combinatorially available way to do so is to glue the reversal to a face-step (a σ_∞ move), because in the dessin identity $\sigma_\infty = (\sigma_0\sigma_1)^{-1}$ the backward vertex motion is paired with the forward motion at the opposite color. But face cycles are precisely the anti-cycles killed by I. Therefore the would-be continuation that realizes a face-step is disallowed by constraint (ii), and the only reduced continuation that remains is the other outgoing arrow b, which lands on the adjacent permitted cycle. □

Corollary 3.4 (Clock interpretation: "reverse" is not an involution on one cycle but a conjugated shift on the neighbor). *In the operator model of Section 3.1, let S_v denote the forward twisted shift on the vertex-cycle Hilbert space $\mathcal{H}_v$. A local reversal at an edge $e = (v, w)$ cannot be implemented as a closed walk that stays entirely on the v-cycle. Instead it is implemented by switching to the adjacent cycle and transporting the shift across the gluing:*

$$\textit{reverse at } e \quad \rightsquigarrow \quad S_v^{-1} \;\simeq\; U_e^{-1}\, S_w^{\pm 1}\, U_e,$$

where U_e is the edge identification/isometry and the sign depends on the chosen local convention for "forward" around w. Because m_v, π_v, e_v need not equal m_w, π_w, e_w, the operator on the right-hand side is generally a different *shift (different dimension and/or different defect factor), exactly as claimed.*

Remark 3.5 (Where total positivity enters the proof pipeline). The forced switching has a practical analytic payoff. Once reversals are realized as *moves between adjacent vertex cycles*, one can draw one-tick evolution (forward steps + switches) as a *planar network* whose local gadgets are the allowed crossings/switches. Assign strictly positive weights to each local gadget (Boltzmann weights, channel Kraus

weights, or learned attention weights). Then the one-tick transfer matrix is the weight matrix of that planar network, hence is totally nonnegative by the Lindström–Gessel–Viennot lemma (Theorem 1.4) and is totally positive under mild irreducibility/strictness assumptions (Corollary 1.5). If, additionally, the weights satisfy a discrete detailed-balance/reflection symmetry so that the transfer matrix is symmetric, then Theorem 1.11 applies and produces a *self-adjoint* Hamiltonian (or modular Hamiltonian) with nonnegative spectrum after an affine normalization. This is the precise sense in which the wiring-diagram/total-positivity technology "proves the result" claimed earlier: it turns purely combinatorial admissibility constraints into a checkable spectral certificate.

4. Classification notes: local hereditary orders, larger twisted shifts, and surface-order gluings

One request for the expanded edition was to fill in "mathematical gaps" around surface-order classification and the operator shifts in larger local vertex orders. This chapter collects the minimum classification statements needed later, together with proof sketches that are standard but easy to lose track of when one jumps between topology, algebra, and physics.

4.1. Hereditary orders over a DVR are endomorphism rings of lattice chains.

Let R be a discrete valuation ring with uniformizer π and fraction field K. Let $V = K^m$.

Definition 4.1 (Lattice and lattice chain). An R-lattice in V is a finitely generated R-submodule $L \subset V$ such that $K \otimes_R L \cong V$. A *lattice chain* of period m is a sequence

$$L_0 \supset L_1 \supset \cdots \supset L_{m-1} \supset \pi L_0$$

with successive quotients L_i/L_{i+1} of rank 1 over the residue field.

Theorem 4.2 (Classical classification of hereditary orders (standard)). *For $A = \mathrm{Mat}_m(K)$, hereditary R-orders in A are precisely endomorphism rings of lattice chains:*

$$\Lambda \textit{ hereditary} \iff \exists\, (L_\bullet) \textit{ lattice chain with } \Lambda = \mathrm{End}_R(L_\bullet),$$

where $\mathrm{End}_R(L_\bullet)$ denotes the set of endomorphisms preserving the entire chain. Moreover, two hereditary orders are conjugate in $\mathrm{GL}_m(K)$ iff their lattice chains are isomorphic (up to shift of indices).

Proof sketch. If Λ is hereditary, its Jacobson radical $J(\Lambda)$ defines a filtration on the unique (up to iso) indecomposable projective modules. Choosing a primitive idempotent gives a lattice whose successive radical powers yield a chain. Conversely, $\mathrm{End}_R(L_\bullet)$ is hereditary because submodules correspond to subchains and projective dimension is controlled by the chain length. □

Remark 4.3. The explicit matrix form (2.1) is obtained by choosing a basis adapted to the chain. In this basis, the (i, j) entry lies in πR precisely when the endomorphism must map L_j into L_i with one valuation drop.

4.2. Normalizer and the larger analogues of the twisted shift.

Fix the standard lattice chain

$$L_i = \pi^i Re_1 \oplus \pi^i Re_2 \oplus \cdots \oplus \pi^i Re_{m-i} \oplus \pi^{i+1} Re_{m-i+1} \oplus \cdots \oplus \pi^{m-1} Re_m,$$

whose endomorphism ring is the Iwahori order (2.1). The twisted shift $S_m(\pi)$ is the unique (up to units) element that cyclically permutes this chain.

More generally, one can introduce *ramification exponent* $e \geq 1$ and define

$$S_m(\pi^e) = \begin{pmatrix} 0 & 0 & \cdots & 0 & \pi^e \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix}, \tag{4.1}$$

which satisfies $(S_m(\pi^e))^m = \pi^e I$.

Proposition 4.4 (Normalizer generator (useful form)). *The normalizer of $\Lambda_m(R)$ in $\mathrm{GL}_m(K)$ is generated by:*

- $\Lambda_m(R)^\times$ *(units of the order),*
- *and the class of $S_m(\pi)$ (or $S_m(\pi^e)$ for the appropriate chain period).*

In particular, any normalizer element induces a permutation (rotation) of the lattice chain, with a valuation factor determined by the number of wrap-arounds.

Remark 4.5 (Clock interpretation). This says: the only genuinely new clock move beyond local gauge (units) is the successor that rotates the chain. Thus the "shift with a π" is not an ad hoc insertion; it is forced by the structure of hereditary orders.

4.3. Surface orders from embedded graphs: classification by local types plus gluing. A surface order in this project is a global object built by gluing local hereditary orders assigned to vertices (cycles) of an embedded graph/dessin. The source text in Appendix A of the volume explains this construction in detail for dessin orders.

We record the abstract classification statement in the language of Section 18.

Theorem 4.6 (Classification template for clocked surface orders). *Fix a surface X with an embedded graph $\Gamma \subset X$ giving a cellular decomposition. A clocked surface order up to Morita equivalence is determined by:*

(1) the underlying cellulation type (combinatorics of Γ),

(2) for each vertex v, a local hereditary order type (equivalently a lattice chain period m_v and ramification exponent e_v),

(3) a gluing cocycle class $[g] \in \check{H}^1(X; \mathrm{Aut}(\Lambda))$ compatible with incidence data,

(4) and (optionally) a choice of clock generators $S_v = S_{m_v}(\pi^{e_v})$ in each stalk (compatible under gluing).

Proof sketch. Local equivalence classes are fixed by Theorem 4.2. Gluing is precisely Čech data up to coboundary, giving H^1-classification of torsors. Morita equivalence suppresses choices of idempotent refinements but preserves local periods and holonomy classes. □

Remark 4.7 (What is still nontrivial). The theorem is a template: to make it fully explicit in a given example, one must compute $\mathrm{Aut}(\Lambda)$, choose the cover, and describe cocycle representatives in terms of the dessin permutations. This is exactly what the source text in Appendix A does in a concrete combinatorial language.

4.4. Why this matters for multiparameter persistence. Multiparameter persistence is most useful when the underlying model space has *strata* and *jump loci*. The classification above supplies those:

- changing (m_v, e_v) moves you between local-order strata (discrete jumps),

- varying the gluing cocycle $[g]$ moves you in a moduli-like space (often discrete but may have continuous parameters if phases are allowed),
- the rank invariants and determinantal jump loci in Appendix B become diagnostics for which stratum you are in (or near).

Thus classification and persistence are not separate topics: classification tells you what "parameters" exist, and persistence tells you which parameters are stable under noisy measurement.

cyclically permutes the indecomposable projective $\mathbb{H}_i$-modules $P_{i,k}$, and it induces an automorphism of $\mathbb{H}_i$ which we also call σ_i. Now, for each cycle $\sigma_p, \sigma_q \in S_{[2m]}$ of σ, we fix an isomorphism

$$\Omega_p/\omega_p \cong \Omega_q/\omega_q.$$

Identifying all such rings, let $\overline{\Omega} = \Omega_i/\omega_i$ for all $\sigma_i \in \Gamma_0$. Let $\pi_i : \Omega_i \to \overline{\Omega}$ be a fixed epimorphism with kernel ω_i. Now, we have a pull-back diagram

$$\begin{tikzcd} \Omega_{p,q} \arrow[r, "\tilde{\pi}_p"] \arrow[d, "\tilde{\pi}_q"'] & \Omega_p \arrow[d, "\pi_p"] \\ \Omega_q \arrow[r, "\pi_q"'] & \overline{\Omega}. \end{tikzcd}$$

which is in general different and non-isomorphic for different choices of π_p and π_q.

Definition 4.8. Let $\mathbb{H} = \prod_{\sigma_i \in \Gamma_0} \mathbb{H}_i$. Let e^i_k be an edge around σ_i, and let $\alpha^{k,l}_{i,j} = (e^i_k, e^j_l)$ be a 2-cycle of the fixed-point free involution α of $C = [\sigma, \alpha, \phi]$ giving the end vertices σ_i and σ_j of the edge $e^i_k \equiv e^j_l$ under the gluing identifying the half-edges e^i_k and e^j_l. It is possible that $\sigma_i = \sigma_j$ if $\alpha^{k,l}_{i,j}$ defines a loop at the vertex σ_i in Γ. We replace the product $\Omega^k_i \times \Omega^l_j$ in $\mathbb{H}_i \times \mathbb{H}_j$ with $\Omega_{i,j}$. This identifies the (k,k) entry of $\mathbb{H}_i$ with the (l,l) entry of $\mathbb{H}_j$, modulo ω. Doing this for all edges of Γ, we get the **Constellation Order** or the (compact) **Gentle Surface Order** $\Lambda := \Lambda(C) = \Lambda(\Gamma)$ associated to the constellation C, or equivalently to the embedded graph $\Gamma \hookrightarrow \Sigma$.

Proposition 4.9. *(1) The indecomposable projective Λ-modules are in bijection with the 2-cycles $(e^i_k, e^j_l) = \alpha^{i,j}_{k,l}$, of $\alpha \in S_{2m}$ for the constellation $C = [\sigma, \alpha, \phi]$. Equivalently, the indecomposable projectives are in bijection with the edges Γ_1. We label them as P_e for $\alpha^{k,l}_{i,j} = e = (e^i_k, e^j_l) \in \Gamma_1$ attached to the vertices σ_i and σ_j.*

(2) Each indecomposable projective Λ-module is a pullback,

$$\begin{tikzcd} P_e \arrow[r] \arrow[d] & P_{i,k} \arrow[d] \\ P_{j,l} \arrow[r] & \overline{\Omega} \end{tikzcd}$$

where the $P_{i,k}$ is an indecomposable projective module in $\mathbb{H}_i$, and $P_{j,l}$ is an indecomposable projective of $\mathbb{H}_j$.

(3) From this we obtain the following commutative diagram with exact rows and columns,

$$\begin{tikzcd}
 & 0 & 0 & 0 & \\
0 \arrow[r] & P_{i,k-1} \arrow[r] \arrow[u] & P_{i,k} \arrow[r] \arrow[u] & \overline{\Omega} \arrow[r] \arrow[u] & 0 \\
0 \arrow[r] & P_{i,k-1} \arrow[r] \arrow[u] & P_e \arrow[r] \arrow[u] & P_{j,l} \arrow[r] \arrow[u] & 0 \\
0 \arrow[r] & 0 \arrow[r] \arrow[u] & P_{j,l-1} \arrow[r] \arrow[u] & P_{j,l-1} \arrow[r] \arrow[u] & 0 \\
 & 0 \arrow[u] & 0 \arrow[u] & 0 \arrow[u] &
\end{tikzcd}$$

(4) $\ker(P_e \to P_{i,k})$ *and* $\ker(P_e \to P_{j,l})$ *are projective* $\mathbb{H}_j$ *and* $\mathbb{H}_i$*-modules respectively, local* Λ*-modules, and are uniserial.*

4.5. A Basic Example.

Example 4.10. Let R have maximal ideal $\mathfrak{m} = \langle m \rangle$, with residue field $k = R/\mathfrak{m}$, and field of fractions $\mathbb{K} = R_{\mathfrak{m}}$. Let Γ be the genus zero graph,

$$\sigma_1 \overset{\alpha_1}{\text{———}} \sigma_2 \overset{\alpha_2}{\text{———}} \sigma_3 \overset{\alpha_3}{\text{———}} \sigma_4$$

given by the constellation $C = [\sigma, \alpha, \phi]$ such that $\sigma = (1)(2,3)(4,5)(6) = \sigma_1\sigma_2\sigma_3\sigma_4$, and $\alpha = (1,2)(3,4)(5,6) = (e_1)(e_2)(e_3)$. We may take

$$\mathbb{H} = \left\{ \begin{pmatrix} a_{11} \end{pmatrix}, \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{pmatrix}, \begin{pmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{pmatrix}, \begin{pmatrix} d_{11} \end{pmatrix} \middle| a_{ij}, b_{ij}, c_{ij}, d_{ij} \in R, b_{12}, c_{12} \in \mathfrak{m} \right\} = \prod_{i=1}^{4} \mathbb{H}_i.$$

We then have the congruences modulo $\mathfrak{m}$,

$$a_{11} \sim b_{11}, b_{22} \sim c_{11}, c_{22} \sim d_{11}.$$

Or in more compact notation which will be used later,

$$(1,1) \sim (2,1), (2,2) \sim (3,1), (3,2) \sim (4,1).$$

We then have

$$\Lambda = \begin{pmatrix} R & 0 & 0 & 0 & 0 & 0 \\ 0 & R & \mathfrak{m} & 0 & 0 & 0 \\ 0 & R & R & 0 & 0 & 0 \\ 0 & 0 & 0 & R & \mathfrak{m} & 0 \\ 0 & 0 & 0 & R & R & 0 \\ 0 & 0 & 0 & 0 & 0 & R \end{pmatrix}$$

such that

$$\lambda_{11} = \lambda_{22}, \lambda_{33} = \lambda_{44}, \lambda_{55} = \lambda_{66}$$

with all equalities taken modulo $\mathfrak{m}$, i.e. the residues λ_{ii} are equal in $k = R/\mathfrak{m}$. [3]

Suppose in particular that

$$\mathbb{H}_1 \cong \mathbb{H}_4 \cong k[[x]], \quad \mathbb{H}_2 \cong \mathbb{H}_3 \cong \begin{pmatrix} k[[x]] & (x)k[[x]] \\ k[[x]] & k[[x]] \end{pmatrix}$$

[3]Notice, the equalities in $k = R/\mathfrak{m}$ (i.e. equalities of residues modulo $\mathfrak{m}$) are given by α in the constellation $C = [\sigma, \alpha, \phi]$.

Letting $\mathfrak{m}_i = (x)$ for $i = 1, ..., 4$, we get a pullback diagram

$$\begin{tikzcd} \Lambda \arrow[r, "\pi_1"] \arrow[d, "\iota_1"'] & \Lambda/\mathrm{rad}(\Lambda) = k^3 \arrow[d] \\ \mathbb{H} \arrow[r, "\pi_2"'] & \mathbb{H}/\mathrm{rad}(\mathbb{H}) = k^6 \end{tikzcd}$$

where $\Omega_i = k[[x]]$ for $i = 1, ..., 4$ and $\omega_i = (x) = \mathrm{rad}(k[[x]])$, so that $\mathrm{rad}(\mathbb{H}_1) = k = \mathrm{rad}(\mathbb{H}_4)$ and $\mathrm{rad}(\mathbb{H}_2) = k \times k = \mathrm{rad}(\mathbb{H}_3)$; and $\mathrm{rad}(\mathbb{H}) = \mathrm{rad}(\Lambda)$. Then we get

$$\Lambda = \begin{pmatrix} k[[x]] & 0 & 0 & 0 & 0 & 0 \\ 0 & k[[x]] & (x)k[[x]] & 0 & 0 & 0 \\ 0 & k[[x]] & k[[x]] & 0 & 0 & 0 \\ 0 & 0 & 0 & k[[x]] & (x)k[[x]] & 0 \\ 0 & 0 & 0 & k[[x]] & k[[x]] & 0 \\ 0 & 0 & 0 & 0 & 0 & k[[x]] \end{pmatrix}$$

such that

$$\lambda_{11} = \lambda_{22}, \lambda_{33} = \lambda_{44}, \lambda_{55} = \lambda_{66}$$

with all equalities taken modulo $\mathfrak{m} = (x) = \omega_i$, i.e. the residues λ_{ii} are equal in k. The automorphisms given by σ on $\mathbb{H}_2 \cong \mathbb{H}_3$ is

$$\begin{pmatrix} 0 & x \\ 1 & 0 \end{pmatrix}$$

Further, this is exactly the algebra associated to the graph

$$\sigma_1 \overset{\alpha_1}{\text{———}} \sigma_2 \overset{\alpha_2}{\text{———}} \sigma_3 \overset{\alpha_3}{\text{———}} \sigma_4$$

5. Projective Resolutions of Simple Objects

In this section we denote by $P^\bullet$ a complex of projective modules

$$\cdots \to P^{-1} \to P^0 \to P^1 \to \cdots$$

over some algebra Λ. Let $\Lambda = \Lambda(C)$ be a gentle constellation order given by the constellation $C = [\sigma, \alpha, \phi]$. [4]

In this section we will show the following,

Proposition 5.1. *Classifying all* 3*-constellations with a fixed passport* $[\lambda_1, \lambda_2, \lambda_3]$ *is equivalent to classifying all "*gentle constellation orders*" with the same normalization, or equivalently all "*closed surface algebras*" with the same normalization.*

Theorem 5.2. *(1) The indecomposable projective modules* $P_e = P_{\alpha_{i,j}}$ *have radical*

$$\mathrm{rad}(P_e) = U(\sigma_i^k) \oplus U(\sigma_j^l)$$

where $U(\sigma_p^q) \cong P_{p,q} \in \mathrm{GrMod}(\mathbb{H}_p)$ *is an indecomposable uniserial* Λ*-module and and indecomposable projective* $\mathbb{H}_p$*-module.*

[4]Question: Find all constellations with fixed monodromy group. (Problem 1.1.10 [55]) Having fixed a group $G \leq S_n$ and a passport $[K_1, ..., K_k]$, all the K_i being conjugacy classes in G, find all the constellations with the cartographic group G and with the refined passport $[K_1, ..., K_k]$ with respect to G.

(2) *The minimal projective resolution of the simple module* $S(\alpha_{i,j}^{k,l}) = S(e_k^i, e_l^j)$ *of* Λ*, corresponding to the vertex* $\alpha_{i,j}^{k,l} = (e_k^i, e_l^j)$ *of* Q[5]*, is infinite periodic. In particular the period* p *of the minimal resolution* $P^\bullet(\alpha_{i,j}^{k,l}) = P^\bullet \to S(\alpha_{i,j}^{k,l})$ *is exactly the least common multiple,*

$$p(P^\bullet(i,j)) = \mathrm{lcm}\{|O_\phi(e_k^i)|, |O_\phi(e_l^j)|\}.$$

where $O_\phi(e_k^i)$ *and* $O_\phi(e_l^j)$ *are the orbits under the action of* ϕ^{-1} *of* e_k^i *and* e_l^j *on the two anti-cycles (or relations in* I*) passing through the vertex* $\alpha_{i,j}^{k,l}$*.*

(3) *The differentials in the minimal projective resolution of the simple module* $S(\alpha_{i,j}^{k,l})$*,* $d^m : P^m \to P^{m+1}$ *in the resolution*

$$P^\bullet(\alpha_{i,j}^{k,l}) : \cdots \to P^m \to P^{m+1} \to \cdots$$

are given by multiplication by the matrix

$$d^m := \begin{pmatrix} a(\phi^{-m} \cdot e_k^i) & 0 \\ 0 & a(\phi^{-m} \cdot e_l^j) \end{pmatrix}.$$

where $a(\phi^{-m} e_k^i) \in Q_1$ *is the arrow with* $ta = \phi^{-m} e_k^i$ *and* $ta(\phi^{-m} \cdot e_l^j) = \phi^{-m} \cdot e_l^j$*.*

(4) *The syzygies* $\Omega^m(\alpha_{k,l}^{i,j}) = \ker(d^m)$ *are of the form*

$$\Omega^m(\alpha_{k,l}^{i,j}) = U\big(\sigma(\phi^{-m}\alpha_{i,j}^{k,l})\big) = U\big(\sigma(\phi^{-m}\sigma e_k^i)\big) \oplus U\big(\sigma(\phi^{-m}\sigma e_l^j)\big).$$

the uniserial modules at the vertex $\sigma\phi^{-m}\sigma e_k^i$ *and* $\sigma\phi^{-m}\sigma e_l^j$ *which are annihilated by left multiplication by the arrows associated to* $\phi_i^{-m}\sigma \cdot e_k^i$ *and* $\phi_i^{-m}\sigma \cdot e_l^j$ *(so* $a : ta = \sigma\phi^{-m}\sigma \cdot e_k^i, b : tb = \sigma\phi^{-m}\sigma \cdot e_l^j \in Q_1$*). Note, there is exactly one such uniserial module for each orbit of the arrows* $a : ta = \phi^{-m-1} e_k^i, b : tb = \phi^{-m-1} e_l^j \in Q_1$ *by definition of the relations* I*.*

The point of the first four statements is to describe the structure of resolutions and the Cohen-Macaulay modules. This will be useful later when explaining how to recover a graph embedded in a Riemann surface entirely in terms of the projective resolutions of the simple modules. The last four statements will provide some invariants which will have some applications to constellations and graphs embedded in Riemann surface. For example, a constellation is self dual if and only if the opposite algebra of the Koszul dual is isomorphic to the algebra $\Lambda(C)$. We will prove this and other things a little later.

Proof. (1) First, $\alpha_{i,j}^{k,l} = (e_k^i, e_l^j) = e$, and with fixed labeling of the edges of $\Gamma(C)$, we have $e_k^i = \sigma_i^{k-1} \cdot e_1^i$, and $e_l^j = \sigma_j^{l-1} \cdot e_l^j$, given by the automorphism

$$\sigma_i^k := \begin{pmatrix} 0 & 0 & \cdots & 0 & \sigma_i \\ 1 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix}^k$$

So, σ_i acts on the algebra $\Lambda = kQ/I$ by left multiplication of e_{j-1}^i (and therefore a_{j-1}^i) by the arrow $\sigma_i a_{j-1}^i = a_j^i$ in the quiver $Q(\Lambda)$. Notice, this multiplication is always nonzero since $\sigma_i = (e_1^i, e_2^i, ..., e_{n_i}^i)$ is a cyclic permutation around the vertex it corresponds to in $\Gamma(C)$, and there is by definition a unique arrow by which σ acts on a given idempotent e_{j-1}^i (and on a_{j-1}^i) lying on this cycle corresponding to the hereditary order $\mathbb{H}_i$ in the pullback diagram defining $\Lambda(C)$.

[5]or equivalently the edge of the same labeling in $\Gamma(C)$ connecting vertex σ_i and σ_j

(2) Let $P(\alpha_{i,j}^{k,l})$ be the projective cover of $S(\alpha_{i,j}^{k,l})$. From the desription of the radical of $P(\alpha_{i,j}^{k,l})$ as the two uniserial module in $\mathbb{H}$ corresponding to the idempotents $\sigma \cdot e_k^i$ and $\sigma \cdot e_l^j$ in $\mathbb{H}_i$ and $\mathbb{H}_j$ respectively, the next term in the resolution is the direct sum of the two indecomposable projective covers $P(\sigma \cdot e_k^i)$ and $P(\sigma \cdot e_l^j)$ in $\mathrm{GrMod}(\Lambda)$. Clearly the kernel of the covering $P(\sigma \cdot e_l^j) \to U(\sigma \cdot e_l^j)$ is exactly the uniserial $U(\sigma\alpha \cdot \sigma \cdot e_l^j)$. Now, $\sigma\alpha = \phi^{-1}$ by defintion of a constellation, so $U(\sigma\alpha \cdot \sigma \cdot e_l^j) = U(\phi^{-1} \cdot \sigma \cdot e_l^j)$, and its projective cover is $P(\phi^{-1} \cdot \sigma \cdot e_l^j)$. The kernel of this covering is $U(\sigma\alpha \cdot (\phi^{-1} \cdot \sigma \cdot e_l^j)) = U(\phi^{-1}\sigma e_k^i)$. This pattern continues also for $\sigma\ell_l^j$, and the terms P^m in the resolution are

$$P(\phi^{-m}\sigma e_k^i) \oplus P(\phi^{-m}\sigma e_l^j).$$

So the terms have indecomposable direct summands which cycle through the orbit of e_k^i and e_l^j under the action of ϕ. The orbits are anit-cycle in I, and the place at which the two cycle meet up at $\alpha_{i,j}^{k,l} = (e_k^i, e_l^j)$ is exactly $p = \mathrm{lcm}\{|O_\phi(e_k^i)|, |O_\phi(e_l^j)|$.

(3) Since the kernel of the cover of a uniserial $P(\alpha_{i,j}^{k,l}) \to U(e_k^i)$ is exactly $U(\sigma e_k^i)$ and it is embedded in $P(\alpha_{i,j}^{k,l})$ as a submodule via multiplication by the arrow $a : ha = \sigma e_k^i$, we get that the differential is indeed,

$$d^m := \begin{pmatrix} a(\phi^{-m} \cdot e_k^i) & 0 \\ 0 & a(\phi^{-m} \cdot e_l^j) \end{pmatrix}.$$

(4)

(5)

(6)

(7)

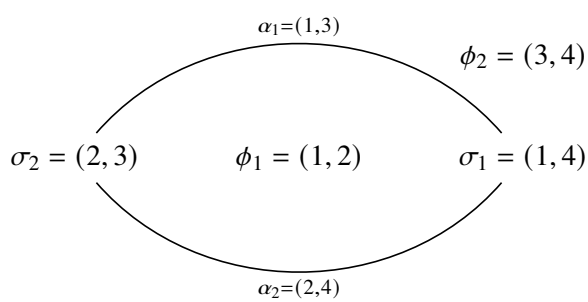
(8)

□

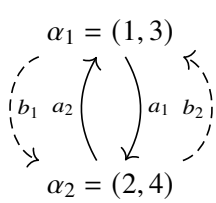
Example 5.3. Let $C = [\sigma, \alpha, \phi]$ be given by

$$\sigma = (1,4)(2,3), \quad \alpha = (1,3)(2,4), \quad \phi = (1,2)(3,4),$$

then $\chi(C) = 2$ and $g(C) = 0$. The embedded graph can be represented by the equator of the sphere with two vertices on it. Or, if we embed it in the plane:



The quiver which comes from this graph is



The associated matrix data is

$$\Lambda = \left\{ \begin{pmatrix} \lambda_{11} & x\cdot\lambda_{12} & 0 & 0 \\ \lambda_{21} & \lambda_{22} & 0 & 0 \\ 0 & 0 & \lambda_{33} & x\cdot\lambda_{34} \\ 0 & 0 & \lambda_{43} & \lambda_{44} \end{pmatrix} \middle| \lambda_{ij} \in k[[x]], \lambda_{22} = \lambda_{33} (\mathrm{mod}\, x) \right\}$$

With normalization

$$\mathbb{H} = \left\{ \begin{pmatrix} \lambda_{11} & x\cdot\lambda_{12} \\ \lambda_{21} & \lambda_{22} \end{pmatrix} \times \begin{pmatrix} \mu_{11} & x\cdot\mu_{12} \\ \mu_{21} & \mu_{22} \end{pmatrix} \middle| \lambda_{ij}, \mu_{kl} \in k[[x]] \right\}$$

and the pullback diagram is given by the relation $(1,2) \sim (2,1), \overline{m} = (2,2)$. The projective resolution of the simple $S(\alpha_1)$ has the following form

$$\cdots \longrightarrow P(\alpha_2) \oplus P(\alpha_2) \xrightarrow{\begin{pmatrix} a_1 & 0 \\ 0 & b_1 \end{pmatrix}} P(\alpha_1) \oplus P(\alpha_1) \xrightarrow{\begin{pmatrix} a_2 & 0 \\ 0 & b_2 \end{pmatrix}} P(\alpha_2) \oplus P(\alpha_2) \xrightarrow{\begin{pmatrix} a_1 & 0 \\ 0 & b_1 \end{pmatrix}} P(\alpha_1) \longrightarrow S(\alpha_1)$$

6. Recovering the Surface

Give the list of projective resolutions of the simple objects, we may completely recover the constellation C, and therefore the Riemann surface and cellularly embedded graph. In fact, we don't need any other information. Neither the surface algebra, nor the medial quiver are needed to recover $C = [\sigma, \alpha, \phi]$, only the projective resolutions of the simples.

7. The Graded Hilbert Function

In many parts of this manuscript we work with *completed* surface algebras/orders (completion at the arrow ideal, or at a maximal ideal $\mathfrak{m}$ in a DVR). Strictly speaking, a completion is *filtered* rather than graded. Nevertheless, for all of the path-counting and determinantal arguments (Cartan determinants, cycle zeta functions, and eventually the Hilbert–Pólya determinant convergence), the relevant object is the *associated graded* algebra/module, which is graded by path length (or by a chosen arrow-weight grading). This is the correct setting for Hilbert functions and Hilbert series.

7.1. Path-length grading and the Hilbert series of an algebra/module. Let k be a field and let $A = kQ/I$ be a bound quiver algebra. Write $J \subset A$ for the arrow ideal (the ideal generated by the images of arrows). Then A is naturally *filtered* by the powers J^n. The associated graded algebra is

$$\mathrm{GrGr}_J(A) \;:=\; \bigoplus_{n\geq 0} J^n/J^{n+1}.$$

When I is homogeneous for the path-length grading (true for the gentle/surface families where I is generated by length-2 relations), $\mathrm{GrGr}_J(A)$ agrees with the usual path-length graded quotient. In either case, the graded pieces measure the number of admissible paths of a given length.

Definition 7.1 (Hilbert function and Hilbert series). Let $M = \bigoplus_{n\geq 0} M_n$ be a $\mathbb{Z}_{\geq 0}$-graded k-vector space (e.g. $M = \mathrm{GrGr}_J(A)$ or a graded A-module). The *Hilbert function* is

$$H_M(n) \;:=\; \dim_k(M_n),$$

and the *Hilbert series* is the formal power series

$$\mathrm{Hilb}_M(q) \;:=\; \sum_{n\geq 0} H_M(n)\, q^n \;\in\; \mathbb{Z}[[q]].$$

Remark 7.2 (Why Hilbert series are the right "partition functions" here). If one interprets path length as an energy/complexity (as we do later in the transfer-operator and modular-Hamiltonian constructions), then $\mathrm{Hilb}_M(q)$ is literally a discrete partition function with fugacity q. Replacing q by e^{-s} or by p^{-s} is exactly the analytic continuation move that connects path-counting to Dirichlet series and Euler products.

7.2. Matrix-valued Hilbert series and the q-Cartan matrix. In noncommutative settings with many primitive idempotents, it is often more informative to keep track of *where* paths start and end.

Let $Q_0 = \{1, \dots, n\}$ and let $\{e_i\}_{i \in Q_0}$ be the primitive orthogonal idempotents of A. Then A decomposes as a matrix of bimodules:

$$A \;\cong\; \bigoplus_{i,j \in Q_0} e_i A e_j.$$

If A is graded (or replaced by $\mathrm{GrGr}_J(A)$), each $e_i A e_j$ is graded.

Definition 7.3 (q-Cartan matrix / matrix Hilbert series). The *q-Cartan matrix* of a graded bound quiver algebra A is the $n \times n$ matrix

$$C_A(q) \;:=\; \big(C_{ij}(q)\big)_{i,j \in Q_0}, \qquad C_{ij}(q) \;:=\; \sum_{m \geq 0} \dim_k\big((e_i A e_j)_m\big)\, q^m.$$

Equivalently, $C_{ij}(q)$ is the generating function counting admissible paths from j to i by length.

Remark 7.4 (Recovering the ordinary Cartan matrix). If A is finite-dimensional and one forgets the grading, then the ordinary Cartan matrix C_A is recovered by evaluation at $q = 1$:

$$(C_A)_{ij} = \dim_k(e_i A e_j) = C_{ij}(1).$$

In general, $C_A(q)$ is defined as a formal power series matrix (or a rational function matrix) even when A is infinite-dimensional.

7.3. Scalar Hilbert series from the q-Cartan matrix. The Hilbert series of the whole algebra is the sum of all matrix entries:

$$\mathrm{Hilb}_A(q) \;=\; \sum_{m \geq 0} \dim_k(A_m)\, q^m \;=\; \sum_{i,j \in Q_0} C_{ij}(q) \;=\; Gr1^{\top} C_A(q)\, Gr1,$$

where $Gr1$ denotes the all-ones column vector. More generally, the Hilbert series of an indecomposable projective $P_j = e_j A$ is

$$\mathrm{Hilb}_{P_j}(q) \;=\; \sum_{i \in Q_0} C_{ij}(q).$$

7.4. Rationality for gentle/surface families. For gentle and locally gentle algebras, admissible paths form a regular language, and the corresponding generating functions are rational. This rationality is made *completely explicit* in terms of oriented cycles by the Bessenrodt–Holm determinant formula for weighted (and hence graded) Cartan matrices (Theorem 4.6, and Corollary 8.4 below in the specialized q-grading). In later chapters this is the key mechanism that lets us treat "cycle sums" and "Euler products" inside a single determinantal package.

8. The Generalized Cartan Matrix

The Cartan matrix is the fundamental "path-counting" invariant of a bound quiver algebra, and in the surface-order setting it is the bridge between:

(i) combinatorics of permitted/forbidden cycles on the embedded graph,
(ii) representation theory (projectives, simples, and resolutions), and
(iii) determinants that factor over cycles (zeta/Euler product analogies).

8.1. Ordinary Cartan matrix and composition multiplicities. Let A be a finite-dimensional k-algebra with primitive orthogonal idempotents $\{e_i\}_{i\in Q_0}$ and indecomposable projectives $P_i = e_iA$. Let $S_i = P_i/\mathrm{rad}(P_i)$ be the corresponding simple modules.

Definition 8.1 (Cartan matrix). The (ordinary) *Cartan matrix* of A is

$$C_A \;:=\; \big(c_{ij}\big)_{i,j\in Q_0}, \qquad c_{ij} \;:=\; [P_j : S_i],$$

the multiplicity of S_i as a composition factor of P_j. Equivalently,

$$c_{ij} = \dim_k \mathrm{Hom}_A(P_i, P_j) = \dim_k(e_iAe_j).$$

In a bound-quiver presentation $A = kQ/I$, the entry c_{ij} is literally the number of admissible paths from j to i (counted with multiplicity in case of relations), because e_iAe_j is spanned by paths from j to i that survive modulo I.

8.2. Graded (or filtered) refinements: the q-Cartan matrix. When A is graded (or replaced by $\mathrm{GrGr}_J(A)$), one refines the Cartan matrix to keep track of the grading.

Definition 8.2 (q-Cartan matrix). For a graded algebra $A = \bigoplus_{m\geq 0} A_m$ with idempotents $e_i \in A_0$, define

$$C_A(q) \;:=\; \big(C_{ij}(q)\big)_{i,j}, \qquad C_{ij}(q) = \sum_{m\geq 0} \dim_k\big((e_iAe_j)_m\big)\, q^m.$$

This is the same object defined in the previous section, viewed now as a *graded Cartan matrix*.

Remark 8.3 (Why this deserves to be called "generalized" in the surface-order setting). If one works with completed surface orders over a DVR R with uniformizer π, then the arrow-ideal filtration and the π-adic filtration are intertwined. One therefore obtains *multi-graded* Cartan data, e.g. a matrix of formal power series in q (path length) and π (valuation/ramification depth). For the present manuscript we mostly keep a single grading variable and treat the rest as parameters inside the weights $w(\alpha)$ of arrows.

8.3. Weighted Cartan matrices and the cycle-product determinant. The key combinatorial input for our later determinant/trace identities is the explicit cycle factorization of $\det C_A(q)$ for locally gentle algebras.

To make the specialization transparent, recall the Bessenrodt–Holm formula (Theorem 4.6): for a weighted locally gentle quiver (Q, I, w),

$$\det C_Q^w(x) = \frac{\prod_{C\in \mathrm{ZC}(Q)}\Big(1 - (-1)^{\ell(C)}\, w(C)\Big)}{\prod_{C\in \mathrm{IC}(Q)}\Big(1 - w(C)\Big)}.$$

Setting all arrow weights equal to q (path-length grading) yields the following useful specialization.

Corollary 8.4 (q-Cartan determinant for locally gentle algebras [44]). *Let (Q, I) be a locally gentle quiver and $A = kQ/I$ equipped with the path-length grading. Then*

$$\det C_A(q) = \frac{\displaystyle\prod_{C\in \mathrm{ZC}(Q)}\Big(1 - (-q)^{\ell(C)}\Big)}{\displaystyle\prod_{C\in \mathrm{IC}(Q)}\Big(1 - q^{\ell(C)}\Big)}. \tag{8.1}$$

Remark 8.5 (Determinants, Hilbert series, and cycle zeta functions). Equation (8.1) is the algebraic version of a dynamical zeta function: a determinant becomes a product over primitive oriented cycles. In later chapters we use exactly this structural fact when matching:

$$\log\det(I - T) \;=\; -\sum_{n\geq 1}\frac{1}{n}\,\mathrm{Tr}(T^n) \qquad \longleftrightarrow \qquad \log L(s,\varpi) \;=\; \sum_{p,k\geq 1}\frac{a_\varpi(p^k)}{k}\,p^{-ks}.$$

9. The Generalized Euler Form

The Euler form is the bilinear pairing that controls both: (i) the weights of quiver semi-invariants (Schofield determinants), and (ii) the inversion relation between Cartan data and Ext data. Because the manuscript uses both *dimension vectors* (representation theory) and *operator traces* (physics), it is worth writing the Euler form carefully and in a form that can be used computationally.

9.1. Euler form via Ext groups (derived-category definition). Let A be a finite-dimensional k-algebra. For A-modules M, N of finite projective dimension (e.g. when A has finite global dimension, or when one restricts to suitable subcategories), define the *Euler form*

$$\langle M, N\rangle_A \;:=\; \sum_{t\geq 0}(-1)^t \;\dim_k \operatorname{Ext}^t_A(M,N). \tag{9.1}$$

This depends only on the classes $[M]$, $[N]$ in the Grothendieck group $K_0(A)$ and extends by bilinearity to a pairing

$$\langle -,-\rangle_A : K_0(A)\times K_0(A)\to\mathbb{Z}.$$

Remark 9.1 (When A has infinite global dimension). Gentle and special-biserial algebras often have infinite global dimension. Nevertheless, the Euler form (9.1) is still meaningful on any full subcategory where the Ext groups are finite-dimensional and eventually vanish (e.g. perfect complexes, or modules admitting eventually periodic resolutions where one works with a graded/refined Euler series). For the Hilbert-series computations below we will primarily use the *graded* (or q-)Euler form, which is defined as a formal series and does not require vanishing in finite degree.

9.2. Euler matrix and the inverse Cartan relation (finite global dimension case). Assume for the moment that A has finite global dimension. Let $\{S_i\}_{i\in Q_0}$ be the simple modules and $\{P_i\}_{i\in Q_0}$ the indecomposable projectives. Write C_A for the Cartan matrix. Define the Euler matrix E_A by

$$(E_A)_{ij} \;:=\; \langle S_i, S_j\rangle_A.$$

Then one has the classical relation

$$E_A \;=\; (C_A^{-1})^\top, \qquad \text{i.e.} \qquad \langle S_i, S_j\rangle_A \;=\; (C_A^{-1})_{ji}. \tag{9.2}$$

Equivalently, in the K_0-basis of projectives one has $\langle P_i, S_j\rangle_A = \delta_{ij}$.

Proof sketch. Take a finite projective resolution of S_i, $0\to P_m\to\cdots\to P_0\to S_i\to 0$, apply $\operatorname{Hom}_A(-,S_j)$, and take alternating sums of dimensions. In matrix form this expresses the identity matrix as the product of the Cartan matrix with the Euler matrix, which is (9.2). □

9.3. Bound quivers and an explicit dimension-vector formula. When $A = kQ/I$ is given by a bound quiver presentation with relations generated by paths of length 2 (the gentle/surface regime), the Euler form can be written directly on dimension vectors. Let $Grd = (d_i)_{i\in Q_0}$ and $Gre = (e_i)_{i\in Q_0}$ be dimension vectors.

Definition 9.2 (Combinatorial Euler form for a bound quiver). Assume (Q, I) has relations generated by a set R of minimal relations, each a linear combination of paths with fixed start and end. Define the bilinear form

$$\langle Grd, Gre\rangle_{(Q,I)} \;:=\; \sum_{i\in Q_0} d_i e_i \;-\; \sum_{a:i\to j\in Q_1} d_i e_j \;+\; \sum_{r:i\Rightarrow j\in R} d_i e_j, \tag{9.3}$$

where $r : i \Rightarrow j$ means that the relation r starts at i and ends at j.

Remark 9.3 (Interpretation). For quivers without relations ($I = 0$) this reduces to the usual Euler/Ringel form $\langle Grd, Gre\rangle = \sum_i d_i e_i - \sum_{a:i\to j} d_i e_j$. The extra $+\sum_r d_i e_j$ term is the first correction in the presence of

relations, and is exact when the algebra has global dimension ≤ 2 (which covers many gentle cases of interest). More generally, higher syzygies contribute further correction terms; in the graded setting one keeps track of them via the q-Euler series below.

9.4. Graded/q-Euler form and inversion of the q-Cartan matrix. For Koszul graded algebras (and in particular for locally gentle algebras with the natural path-length grading [44]), one can package the entire Ext tower into a generating series.

Definition 9.4 (q-Euler matrix). Let A be a graded algebra and let S_i be the graded simples. Define the q-Euler matrix

$$E_A(q) \;:=\; \big(E_{ij}(q)\big)_{i,j}, \qquad E_{ij}(q) := \sum_{t\geq 0}(-1)^t \,\dim_k \operatorname{Ext}^t_A(S_i, S_j)\, q^t.$$

When A is Koszul, one has the standard Koszul inversion relation

$$C_A(q)\, E_A(-q)^\top \;=\; I, \qquad \text{equivalently} \qquad E_A(q) \;=\; \big(C_A(-q)^{-1}\big)^\top. \tag{9.4}$$

Thus the q-Cartan matrix is the matrix Hilbert series of projectives, while the q-Euler matrix is the matrix Poincaré series of Ext between simples.

Remark 9.5 (Hilbert series from Euler form computations). Equation (9.4) is precisely the computational principle requested in the "expanded" instructions: *once the Euler form/Ext series is known (e.g. from explicit projective resolutions of simples), one can recover the graded Cartan data and hence the Hilbert series by matrix inversion, and conversely.* In the gentle/surface setting, explicit periodic resolutions make $E_A(q)$ rational, hence $C_A(q)$ and $\mathrm{Hilb}_A(q)$ are rational as well.

9.5. Euler form and weights of determinantal semi-invariants. Finally, we record the Euler-form identity that explains why the pairing is indispensable in the invariant theory used later.

Let $A = kQ/I$ and fix a dimension vector Grd. For any A-module M of dimension vector Grm, the Schofield/Derksen–Weyman theory associates a character (weight)

$$\theta_M \in \mathbb{Z}^{Q_0} \cong X^*(G_Grd), \qquad \theta_M(i) := \langle Grm, Gre_i\rangle_{(Q,I)},$$

where Gre_i is the ith standard basis vector. The dimension-match condition for the determinantal semi-invariant c^M (Definition 4.2) is exactly the vanishing of the Euler pairing

$$\langle Grm, Grd\rangle_{(Q,I)} = 0,$$

and the resulting determinant c^M lies in the weight space $\mathcal{SI}(A, Grd)_{\theta_M}$. This is the conceptual reason that the Euler form sits at the intersection of:

(i) determinantal invariant theory (semi-invariants as determinants),
(ii) toric degeneration (weights become lattice points), and
(iii) the arithmetic transfer-operator model (weights become prime-power phases).

CHAPTER 8

Examples: Double Simple Cycle Algebras

Although it is not phrased in these terms, in [56] Kraskiewicz and Weyman study a class of finite dimensional gentle algebras $A(n)$ given by the following pullback diagram with $\mathbb{A}_n$ the equioriented type $\mathbb{A}$ quiver with $|Q_0| = n$.

$$\begin{tikzcd} A(n) \arrow[r, "\pi_1"] \arrow[d, "\iota_1"'] & \mathrm{top}(A(n)) \arrow[d, "\iota_2"] \\ k\mathbb{A}_n \times k\mathbb{A}_n \arrow[r, "\pi_2"'] & \mathrm{top}(k\mathbb{A}_n \times k\mathbb{A}_n) \end{tikzcd}$$

The maps π_1, π_2 are the projections onto $\mathrm{top}(A(n)) = A(n)/\mathrm{rad}(A(n)) = \bigoplus_{i=1}^n P(i)/\mathrm{rad}(P(i)) \cong \prod_{i=1}^n k$, $\mathrm{top}(k\mathbb{A}_n \times k\mathbb{A}_n) = k\mathbb{A}_n/\mathrm{rad}(k\mathbb{A}_n) \times k\mathbb{A}_n/\mathrm{rad}(k\mathbb{A}_n) \cong \prod_{i=1}^n k \times \prod_{i=1}^n k$. The maps ι_1, ι_2 are idempotent embeddings given by $e_i \mapsto e_i' + e_i''$, where e_i is the ith primitive idempotent of the algebra $A(n)$, e_i' is the primitive idempotent in the first copy of $k\mathbb{A}_n$ corresponding to the vertex $i \in \mathbb{A}_{n,0}$, and e_i'' is the ith idempotent of the second copy. We would like to study a class of algebras closely related to these algebras. Let $\tilde{\mathbb{A}}_n$ be the cyclicly oriented quiver with n arrows and vertices. For $n = 0 \pmod 2$, let $\Lambda(n)$ be given by the matrix algebra

$$\Lambda(n) := \begin{pmatrix} \lambda_{11} & (x)\lambda_{12} & \cdots & (x)\lambda_{1,n-1} & (x)\lambda_{1,n} \\ \lambda_{11} & \lambda_{12} & \cdots & (x)\lambda_{1,n-1} & (x)\lambda_{1,n} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \lambda_{n-1,1} & \lambda_{n-1,2} & \cdots & \lambda_{1,n-1} & (x)\lambda_{1,n} \\ \lambda_{n1} & \lambda_{n2} & \cdots & \lambda_{n,n-1} & \lambda_{n,n} \end{pmatrix} \times \begin{pmatrix} \mu_{11} & (x)\mu_{12} & \cdots & (x)\mu_{1,n-1} & (x)\mu_{1,n} \\ \mu_{11} & \mu_{12} & \cdots & (x)\mu_{1,n-1} & (x)\mu_{1,n} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \mu_{n-1,1} & \mu_{n-1,2} & \cdots & \mu_{1,n-1} & (x)\mu_{1,n} \\ \mu_{n1} & \mu_{n2} & \cdots & \mu_{n,n-1} & \mu_{n,n} \end{pmatrix},$$

where $\lambda_{ij}, \mu_{ij} \in k[[x]]$, $\lambda_{ii} = \mu_{ii} \pmod x$, which is given by the pullback diagram

$$\begin{tikzcd} \Lambda(n) \arrow[r, "\pi_1"] \arrow[d, "\iota_1"'] & \Lambda(n)/\mathrm{rad}(\Lambda(n)) \arrow[d, "\iota_2"] \\ \mathbb{H}(n) \arrow[r, "\pi_2"'] & \mathbb{H}(n)/\mathrm{rad}(\mathbb{H}(n)) \end{tikzcd}$$

where

$$\mathbb{H}(n) = \begin{pmatrix} \lambda_{11} & (x)\lambda_{12} & \cdots & (x)\lambda_{1,n-1} & (x)\lambda_{1,n} \\ \lambda_{11} & \lambda_{12} & \cdots & (x)\lambda_{1,n-1} & (x)\lambda_{1,n} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \lambda_{n-1,1} & \lambda_{n-1,2} & \cdots & \lambda_{1,n-1} & (x)\lambda_{1,n} \\ \lambda_{n1} & \lambda_{n2} & \cdots & \lambda_{n,n-1} & \lambda_{n,n} \end{pmatrix} \times \begin{pmatrix} \mu_{11} & (x)\mu_{12} & \cdots & (x)\mu_{1,n-1} & (x)\mu_{1,n} \\ \mu_{11} & \mu_{12} & \cdots & (x)\mu_{1,n-1} & (x)\mu_{1,n} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \mu_{n-1,1} & \mu_{n-1,2} & \cdots & \mu_{1,n-1} & (x)\mu_{1,n} \\ \mu_{n1} & \mu_{n2} & \cdots & \mu_{n,n-1} & \mu_{n,n} \end{pmatrix},$$

with $\lambda_{ij}, \mu_{ij} \in k[[x]]$. Then, $\mathrm{rad}(\mathbb{H}(n)) = \mathrm{rad}(\Lambda(n))$, and ι_1 and ι_2 are given by radical embeddings with mapping on the idempotents:

$$\Lambda(n)/\mathrm{rad}(\Lambda(n)) \ni e_{ii} \mapsto e_{ii}' + e_{ii}'' \in \mathbb{H}(n)/\mathrm{rad}(\mathbb{H}(n)).$$

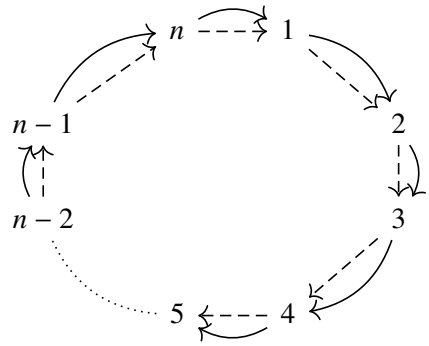
Now, if $n = 1 \pmod 2$, then we take

$$\Lambda(n) := \begin{pmatrix} \lambda_{11} & (x)\lambda_{12} & \cdots & (x)\lambda_{1,n-1} & (x)\lambda_{1,n} \\ \lambda_{11} & \lambda_{12} & \cdots & (x)\lambda_{1,n-1} & (x)\lambda_{1,n} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \lambda_{n-1,1} & \lambda_{n-1,2} & \cdots & \lambda_{1,n-1} & (x)\lambda_{1,n} \\ \lambda_{n1} & \lambda_{n2} & \cdots & \lambda_{n,n-1} & \lambda_{n,n} \end{pmatrix}$$

with $\lambda_{ij} \in k[[x]]$, and $\lambda_{ii} = \lambda_{2i,2i} \pmod x$, for $i = 1, 2, ..., n$. We have

$$\mathbb{H}(n) = \begin{pmatrix} \lambda_{11} & (x)\lambda_{12} & \cdots & (x)\lambda_{1,n-1} & (x)\lambda_{1,n} \\ \lambda_{11} & \lambda_{12} & \cdots & (x)\lambda_{1,n-1} & (x)\lambda_{1,n} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \lambda_{n-1,1} & \lambda_{n-1,2} & \cdots & \lambda_{1,n-1} & (x)\lambda_{1,n} \\ \lambda_{n1} & \lambda_{n2} & \cdots & \lambda_{n,n-1} & \lambda_{n,n} \end{pmatrix}$$

with $\lambda_{ij} \in k[[x]]$, and the pullback diagram is the same with the new $\Lambda(n)$ and $\mathbb{H}(n)$. We call $\mathbb{H}(n)$ the **normalization** of the order $\Lambda(n)$. We will call $\Lambda(n)$ a **double simple cycle order**. In general, we may replace $k[[x]]$ by any R such that R is a complete noetherian local domain, and we then replace (x) with $\mathfrak{m}$, the maximal ideal of R. For $R = k[[x]]$ and $\mathfrak{m} = (x)$, the order $\Lambda(n)$ is isomorphic to the completion of the path algebra:



where the relations $I = \langle a_{i+1}a_i, b_{i+1}b_i \rangle_{i=1}^n$ is given by composition of two arrows of the same color. We then have a pullback diagram

$$\begin{tikzcd} \tilde{A}(n) \arrow[r, "\pi_1"] \arrow[d, "\iota_1"'] & k^n \arrow[d, "\iota_2"] \\ k\tilde{\mathbb{A}}_n \times k\tilde{\mathbb{A}}_n \arrow[r, "\pi_2"'] & k^n \times k^n \end{tikzcd}$$

for n odd, and

$$\begin{tikzcd} \tilde{A}(n) \arrow[r, "\pi_1"] \arrow[d, "\iota_1"'] & k^n \arrow[d, "\iota_2"] \\ k\tilde{\mathbb{A}}_{2n} \times \arrow[r, "\pi_2"'] & k^{2n} \end{tikzcd}$$

for n even. We will call $\tilde{A}(n)$ the class of **double simple cycle algebras**.

0.1. The Riemann Surfaces. Let $\tilde{A}(n) = kQ/I$ be a double simple cycle algebra of length n. Then $I = \langle a_{i+1}a_i, b_{i+1}b_i \rangle_{i \in \mathbb{Z}/n\mathbb{Z}}$. In particular, there are two cycles, up to cyclic permutation, "R" and "B" of

length n, such that any two consecutive arrows lies in I, and there is a single unique non-zero cycle (not in I) of length $2n$,

$$C = (a_1 b_2 a_3 b_4 \cdots b_1 a_2 b_3 a_4 b_5 \cdots a_{n-1} b_n)$$

up to a cyclic permutation of the arrows if n is even, and there are two

$$C_1 = (a_1 b_2 a_3 \cdots a_{n-1} b_n), \quad C_2 = (b_1 a_2 b_3 \cdots b_{n-1} a_n)$$

if n is odd. Let $\varphi = \varphi_R \varphi_B \in S_{Q_1}$ be two cyclic permutations in the permutation group $S_{Q_1} \cong S_{2n}$. Let $\varphi_R = (a_1, a_2, ..., a_n) \mapsto (1, 2, ..., n)$ and $\varphi_B = (b_1, b_2, ..., b_n) \mapsto (n+1, n+2, ..., 2n)$ given by identifying Q_1 with $[2n]$ by fixing a labeling of the arrows. Let

$$\sigma = \begin{cases} (a_1 b_2 a_3 b_4 \cdots b_1 a_2 b_3 a_4 b_5 \cdots a_{n-1} b_n) & \text{if } |Q_0| = 2k+1 \\ (a_1, b_2, a_3, ..., b_{n-2}, a_{n-1}, b_n)(b_1, a_2, b_3, ..., a_{n-2} b_{n-1} a_n) & \text{if } |Q_0| = 2k \end{cases}$$

In the above cases we may identify,

$$(a_1 b_2 a_3 b_4 \cdots b_1 a_2 b_3 a_4 b_5 \cdots a_{n-1} b_n) \mapsto (1, n+1, 2, n+2, ..., n, 2n) \in S_{2n}$$

and

$$\begin{aligned} &(a_1, b_2, a_3, ..., b_{n-2}, a_{n-1}, b_n)(b_1, a_2, b_3, ..., a_{n-2} b_{n-1} a_n) \\ &\qquad \mapsto (1, n+2, 3, ..., n-1, 2n)(n+1, 2, n+3, ..., 2n-1, n) \in S_{2n}. \end{aligned}$$

for $k = 0, 1, 2, ...$; finally, let $\alpha = (1, n+1)(2, n+2) \cdots (n, 2n)$. If we restrict I to R or B, we have an algebra $\Lambda_R = kR/I \cong k\tilde{\mathbb{A}}_n/\mathrm{rad}(k\tilde{\mathbb{A}}_n)^2 \cong kB/I = \Lambda_B$. We may then view α as the gluing that identifies $ta'_i \leftrightarrow tb'_i$, where $a'_i \in \Lambda_R$ and $b'_i \in \Lambda_B$ are arrows in the respective algebras. It is not hard to verify $\sigma\alpha = \varphi^{-1}$, and thus the triple $[\sigma, \alpha, \varphi]$ may be seen as a combinatorial embedding of a graph into a Riemann surface. This map $\Gamma(n) \hookrightarrow X$ has either one vertex if n is even, or two vertices if n is odd, corresponding to σ. It has two faces, corresponding to φ_R and φ_B; it also has exactly $n = |Q_0|$ edges corresponding to α. Thus we may compute the surface associated to the algebra $\tilde{A}(n)$ via

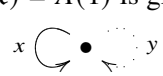
$$\chi(\tilde{A}(n)) = |\sigma| - |\alpha| + |\varphi| = \begin{cases} 2 - 2k & \text{if } |Q_0| = n = 2k+1 \\ 4 - 2k & \text{if } |Q_0| = n = 2k \end{cases} .$$

for $k = 0, 1, 2, ...$, and $n \geq 1$, so that we have the genus function

$$g(\tilde{A}(n)) = \begin{cases} k & \text{if } n = 2k+1 \\ k-1 & \text{if } n = 2k \end{cases}$$

1. Genus 0 Examples

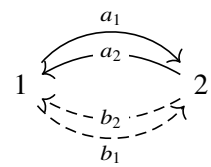
1.1. The Dihedral Ringel Algebra $\tilde{A}(1)$. Let $\sigma = (1, 2), \alpha = (1, 2), \phi = (1)(2)$. Then the closed surface algebra $\Lambda(\mathfrak{c})$ given by the constellation $\mathfrak{c}_1 = [\sigma, \alpha, \varphi]_0$ is given by the graph with one vertex and one loop embedded in the sphere. In particular $\Lambda(\mathfrak{c}) = \tilde{A}(1)$ is given by the quiver



and is isomorphic to $k\langle x, y\rangle/\langle x^2, y^2\rangle$. Any representation of this quiver is a pair $(X, Y) \in \mathrm{End}(V) \times \mathrm{End}(V)$ of nilpotent operators on a vector space V

1.2. $\tilde{A}(2)$. Let $\mathfrak{c}_2 = [\sigma, \alpha, \varphi]_2$ be given by $\sigma = (1, 4)(2, 3)\alpha = (1, 3)(2, 4), \varphi = (1, 2)(3, 4)$, then $\chi(\mathfrak{c}_2) = 2$ and $g(\mathfrak{c}_2) = 0$. The embedded graph can be represented by the equator of the sphere with two

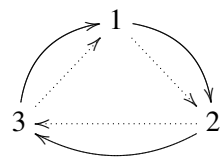
vertices on it. The quiver which comes from this graph is



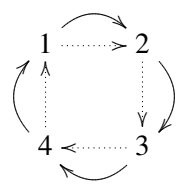
2. Genus 1 Examples

2.1. $\tilde{A}(3)$**.** Let $\mathfrak{c}_3 = [\sigma, \alpha, \varphi]_3$ be defined by $\sigma = (1,6,2,4,3,5), \alpha = (1,4)(2,5)(3,6), \varphi = (1,2,3)(4,5,6)$. Then we have $\chi(\mathfrak{c}_3) = 1 - 3 + 2 = 0$ so $g(\mathfrak{c}_3) = 1$. The graph embedded on the torus can be obtained by the following gluing of the square to obtain the torus,

the quiver is then,



2.2. $\tilde{A}(4)$**.** Let $\mathfrak{c}_4 = [\sigma, \alpha, \varphi]_4$ be given by $\sigma = (1,8,3,6)(2,5,4,7), \alpha = (1,5)(2,6)(3,7)(4,8), \varphi = (1,2,3,4)(5,6,7,8)$ $\chi(\mathfrak{c}_4) = 2 - 4 + 2$ so $g(\mathfrak{c}_4) = 1$.

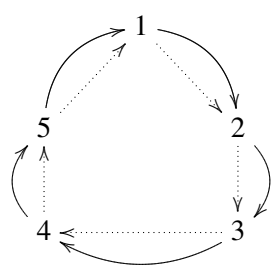


3. Genus 2 Examples

3.1. $\tilde{A}(5)$**.** The constellation $\mathfrak{c}_5 = [\sigma, \alpha, \varphi]_5$ is defined by,

- $\sigma = (1,10,4,8,2,6,5,9,3,7)$,
- $\alpha = (1,6)(2,7)(3,8)(4,9)(5,10)$,
- $\varphi = (1,2,3,4,5)(6,7,8,9,10)$.

$\chi(\mathfrak{c}_5) = 1 - 5 + 2 = -2$, so $g(\mathfrak{c}_5) = 2$.



3.2. $\tilde{A}(6)$**.** The constellation $\mathfrak{c}_6 = [\sigma, \alpha, \varphi]_6$ is defined by,

- $\sigma = (1,12,5,10,3,8)(2,7,6,11,4,9)$,
- $\alpha = (1,7)(2,8)(3,9)(4,10)(5,11)(6,12)$,
- $\varphi = (1,2,3,4,5,6)(7,8,9,10,11,12)$.

The quiver of $\tilde{A}(6)$ is then,

Part 4

Representation Varieties and Rings of Relative Invariants

CHAPTER 9

Background on Representation Theory of General Linear Groups

1. Young Tableaux and Schur Functors

A **partition** $\lambda \vdash m$, of some nonnegative integer m is a sequence of nonincreasing numbers $\lambda = (\lambda_1, ..., \lambda_s)$ such that $\sum_i \lambda_i = m$. We define a **Young diagram** corresponding to a partition $\lambda = (\lambda_1, ..., \lambda_s) \vdash m$, as the diagram with λ_i boxes in the ith row. We identify partitions with their Young diagrams and speak of the two interchangeably. For a free module E over a commutative ring K with ordered basis $\{e_1, ..., e_n\}$, we associate a filling of the diagram λ by integers $\{1, ..., n\}$ to an element in the module

$$\bigwedge^{\lambda_1} E \otimes \cdots \otimes \bigwedge^{\lambda_s} E$$

as follows: If in row i and box j of λ we have the integers $t(i, j)$ for $j = 1, ..., \lambda_i$, we associate the element

$$e_{t(1,1)} \wedge \cdots \wedge e_{t(1,\lambda_1)} \otimes \cdots \otimes e_{t(s,1)} \wedge \cdots \wedge e_{t(s,\lambda_s)}.$$

We define such a filling to be a **tableaux**. A tableaux is **standard** if its rows are strictly increasing, and its columns are nondecreasing.

Fix a free module E of rank n over a commutative ring K. Let $\lambda = (\lambda_1, ..., \lambda_s) \vdash m$ be a partition. We define the module

$$L_\lambda E = \bigwedge^{\lambda_1} \otimes \cdots \otimes \bigwedge^{\lambda_s} E / R(\lambda, E)$$

where the submodule $R(\lambda, E)$ is the sum of all submodules of the form

$$\bigwedge^{\lambda_1} E \otimes \cdots \otimes \bigwedge^{\lambda_{a-1}} E \otimes R_{a,a+1}E \otimes \bigwedge^{\lambda_{a+2}} E \otimes \cdots \otimes \bigwedge^{\lambda_s} E$$

for $1 \leq a \leq s - 1$. Here $R_{a,a+1}E$ is the submodule spanned by the images of the maps $\theta(\lambda, a, u, v, E)$

$$\begin{tikzcd}
\bigwedge^u E \otimes \bigwedge^{\lambda_a - u + \lambda_{a+1} - v} E \otimes \bigwedge^v E \arrow[d, "1\otimes\Delta\otimes 1"] \\
\bigwedge^u E \otimes \bigwedge^{\lambda_a - u} E \otimes \bigwedge^{\lambda_{a+1} - v} E \bigwedge^v E \arrow[d, "m_{12}\otimes m_{34}"] \\
\bigwedge^{\lambda_a} E \otimes \bigwedge^{\lambda_{a+1}} E
\end{tikzcd}$$

Here, Δ is the diagonal embedding (or comultiplication), and $m : \bigwedge^r E \otimes \bigwedge^s E \to \bigwedge^{r+s} E$ is a component of the multiplication map on the exterior algebra $\bigwedge^\bullet E$. Combinatorially, we may use the theory of Young tableaux to describe the modules $L_\lambda E$. It is well known the standard tableaux form a basis of $L_\lambda E$. Further, the relations $R(\lambda, E)$ may be visualized as follows. Let $\lambda \vdash m$ be a partition with at most n parts. To the map $\theta(\lambda, a, u, v, E)$ we associate a **Young scheme**. The Young scheme is defined as being a diagram of shape λ with empty boxes everywhere except the ath and $a + 1^{st}$ rows. In row a there are u empty boxes followed by $\lambda_a - u$ filled boxes. In row $a + 1$ there are $\lambda_{a+1} - v$ filled boxes followed by v empty boxes. We

restrict to $u + v < \lambda_{a+1}$ as in the definition of $L_\lambda E$. Let $U_j = e_{t(j,1)} \wedge \cdots \wedge e_{t(j,\lambda_j)}$, $V_1 = e_{x_1} \wedge \cdots \wedge e_{x_u}$, $V_2 = e_{y_1} \wedge \cdots \wedge e_{y_{\lambda_a - u + \lambda_v - v}}$, and $V_3 = e_{z_1} \wedge \cdots \wedge e_{z_v}$. Then the image of a typical element

$$U_1 \otimes \cdots \otimes U_{a-1} \otimes V_1 \otimes V_2 \otimes V_3 \otimes U_{a+2} \otimes \cdots \otimes U_s$$

is a sum of tableaux where we put $x_1, ..., x_u$ in the empty u boxes in row a, and $z_1, ..., z_v$ in the empty v boxes of row $a + 1$, and we shuffle the elements $y_1, ..., y_{\lambda_a - u + \lambda_{a+1} - v}$ between the filled boxes in row a and $a + 1$. The coefficients of the tableaux in the summation are ± 1 depending on the sign of the permutations coming from the exterior diagonals.[1]

2. Standard Monomials,The Straightening Law, and Determinantal Varieties

2.1. Standard Monomials and Straightening Laws. Let us now introduce the notion of a standard monomial theory.

Definition 2.1. Let R be a ring and let A be a commutative R-algebra, and let $S := \{s_1, ..., s_N\} \subset R$ have a partial order $\leq$.

(1) An ordered product $s_{i_1} \cdots s_{i_k}$ of elements from S is said to be a **standard monomial** if the elements appear in nondecreasing order, with respect to the partial order $\leq$.

(2) We say A has a **standard monomial theory for** S if the standard monomials for a basis of A over R.

(3) If $s, s' \in S$ are incomparable in the partial order $\leq$, we have a unique expression called a **straightening law**:

$$s \cdot s' = \sum_i c_i M_i, \quad c_i \in R, M_i \text{ standard.}$$

If a monomial $s_{i_1} \cdots s_{i_k}$ is nonstandard we may replace it with a standard one as follows. If there is a product $s \cdot s'$ in $s_{i_1} \cdots s_{i_k}$ with $s > s'$ we replace if with $s' \cdot s$. If s and s' are incomparable, we replace $s \cdot s'$ with $s \cdot (\sum_i c_i M_i)$.

(4) We say the R-algebra A has a **straightening law** if the previous replacement algorithm always terminates after finitely many steps.

We define a **standard bi-tableau**[2], denoted $(s|t)$ as a pair of standard tableaux s and t of the same shape λ, where by convention we write s in reverse order. To a bitableau we associate a product of minors of X, where the entries of row a of s give the columns and the entries of row a of t give the rows of the minor of X. Then each pair of rows in s and t defines a minor of size λ_a, and the bi-tableau is associated to the product of these minors. It is well known that the standard bi-tableaux with at most $\min\{\dim E, \dim F\}$ columns forms a K-free basis of $K[E^* \otimes F]$, and that the standard bi-tableaux with at most k columns form a K-free basis of R/I_{k+1}. We call the associated minors to a standard bi-tableau a *standard monomial* in R or R/I_{k+1}. It can be shown that any nonstandard monomial can be written as a sum of standard monomials

[1]From now on, we will let $L_\lambda F$ denote the Schur functor corresponding to the diagram λ, and we will let $S_{(\lambda-k)}F = L_\lambda F \otimes (\bigwedge^{\dim F} F^*)^{\otimes k}$, where $\lambda - k$ is obtained by subtracting the integer k from every entry of the vector λ.

[2]An archetypal example of bi-tableaux and an algebra with straightening law and standard monomial theory is the algebra $\mathcal{G}\nabla\mathcal{S}\dagger\Updownarrow(V \otimes W^*)$ for two vector spaces V and W, or more generally, let $X = (x_{ij})$ be a matrix of indeterminates so that $X \in \mathrm{Hom}_K(E, F) = E^* \otimes F$, where E and F are two free $\mathbb{Z}$-modules. Define the ring $R = \mathbb{Z}[X] = \mathbb{Z}[x_{ij}]$, to be the polynomial ring in the indeterminates (x_{ij}), and let $\{e_1, ..., e_m\}$ and $\{f_1, ..., f_n\}$ be ordered bases of E and F respectively. There is a natural action of the group $G = \mathrm{GL}(E) \times \mathrm{GL}(F)$ on R induced by the action on X define by $(A, B) \cdot X = A^{-1}XB$. If K is a field, the orbits in $\mathrm{Hom}_K(E, F)$ are classified by ranks, and the orbit closures of maps of rank k say, are all maps of rank $\leq k$. The action of G on R is more complicated. If E and F are free K-modules for a field K, and V_k is the orbit closure of rank k maps, then the defining ideal of V_k is $I_{k+1} = R(\bigwedge^{k+1} E^* \otimes \bigwedge^{k+1} F)$ generated by minors of size $k + 1$, and the coordinate ring R/I_{k+1} is normal and Cohen Macaulay. A classical characteristic free approach using the Schur functors allows one to define a basis of $\mathbb{K}[E^* \otimes F]$ in terms of certain *standard monomials* given by standard bi-tableaux.

each of which are earlier in the partial order on monomials. In particular if M is nonstandard then we can write $M = \sum_i n_i M_i + \sum_j n_j M_j$, where M_i are standard and of the same shape as the tableau corresponding to M, and the M_j are standard but of a smaller shape in the order on tableau.

Let $GrGr(n, m+n)$ denote the Grassmannian variety of n-dimensional subspaces of an $(m+n)$-dimensional vector space V. Let $\{w_1, ..., w_n\}$ be a basis for an n-dimensional subspace $W \subset V$. Then the vector $w_1 \wedge \cdots \wedge w_n$ determines a point $[W]$ in the projective space $\mathbb{P}(\bigwedge^n V)$, and the map $W \mapsto [W]$ is a one-to-one correspondence between n-dimensional subspaces of V and points in $\mathbb{P}(\bigwedge^n V)$ (which are lines in $\bigwedge^n V$). For the standard basis $\{e_i\}_{i=1}^{m+n}$ of V, we have the standard basis $\{e_{i_1} \wedge \cdots \wedge e_{i_n} : i_1 < \cdots < i_n\}$ of $\bigwedge^n V$. If to any $v_1 \wedge \cdots \wedge v_n \in \bigwedge^n V$ we associate the matrix

$$X = \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix} = \begin{pmatrix} v_{1,1} & v_{1,2} & \cdots & v_{1,m+n} \\ v_{2,1} & v_{2,2} & \cdots & v_{2,m+n} \\ \vdots & \vdots & \ddots & \vdots \\ v_{n,1} & v_{n,2} \& \cdots & v_{n,m+n} & \end{pmatrix},$$

we have that in the basis $\{e_{i_1} \wedge \cdots \wedge e_{i_n} : i_1 < \cdots < i_n\}$ the coordinates of $v_1 \wedge \cdots \wedge v_n$ are given by the maximal minors of X. Let $[i_1, i_2, ..., i_n]$ denote the minor given by columns $i_1, i_2, ..., i_n$ of X. So,

$$v_1 \wedge \cdots \wedge v_n = \sum_{1 \le i_1 \le \cdots \le i_n \le m+n} [i_1, ..., i_n] e_{i_1} \wedge \cdots \wedge e_{i_n}.$$

The open set $S_{n,m+1} = \{(v_1, ..., v_n) \in V^n : v_1 \wedge \cdots \wedge v_n \neq 0\} \subset \mathrm{Hom}(K^{m+n}, K^n)$ of maximal rank $n \times (m+n)$-matrices is called the **Stiefel manifold**. Now, $GrGr(n, m+n)$ can be identified with the orbits in $S_{n,m+n} \subset \mathrm{Hom}(K^{m+n}, K^n)$ under the action of $\mathrm{GL}(n, K)$ by left multiplication. Further, given a homomorphism $\pi : K^r \to K^{r+s}$ of two affine spaces, of the form

$$\pi(x_1, ..., x_r) = (x_1, ..., x_r, p_1, ..., p_s)$$

where p_i are polynomials in the x_j, the image of π is a closed subvariety of K^{r+s}, and π is an isomorphism of K^r onto its image (it is the *graph* of a polynomial map). The defining ideal is $I = (x_{r+i} - p_i)$, and the inverse map is

$$(x_1, ..., x_r, ..., x_{r+s}) \mapsto (x_1, ..., x_r).$$

Now, consider the open set U of $GrGr(n, m+n)$ where the Plücker coordinate given by the minor coming from the last n columns is nonzero. U can be identified with the space of $n \times m$ matrices. The association is given by associating any X with the row span of the matrix

$$(X|\tilde{\mathrm{id}}_n) = \begin{pmatrix} x_{11} & \cdots & x_{1m} & 0 & \cdots & 0 & 1 \\ x_{21} & \cdots & x_{2m} & 0 & \cdots & 1 & 0 \\ \vdots & \ddots & \vdots & \vdots & & \vdots & \vdots \\ x_{n1} & \cdots & x_{nm} & 1 & \cdots & 0 & 0 \end{pmatrix}.$$

One may now identify Plücker coordinates with **bi-tableaux**.

Example 2.2. Let $n = 3$, $m = 5$, and write

$$X = \begin{pmatrix} x_{31} & x_{32} & x_{33} & x_{34} & x_{35} & 1 & 0 & 0 \\ x_{21} & x_{22} & x_{23} & x_{24} & x_{25} & 0 & 1 & 0 \\ x_{11} & x_{12} & x_{13} & x_{14} & x_{15} & 0 & 0 & 1 \end{pmatrix}.$$

Now let the Plücker coordinate $[1,2,3][1,2,5][1,2,7][2,3,6][5,6,7][5,6,8]$ be represented by the tableau

$$\begin{array}{|c|c|c|}\hline 1&2&3\\\hline 1&2&5\\\hline 1&2&7\\\hline 2&3&8\\\hline 5&6&7\\\hline 5&6&8\\\hline\end{array}. \qquad (*)$$

To this we may associate the bi-tableau

$$\left(\begin{array}{|c|c|c|}\hline 1&2&3\\\hline 1&2&3\\\hline \end{array}\begin{array}{|c|c|}\hline 1&3\\\hline 1&2\\\hline \end{array}\begin{array}{|c|}\hline 1\\\hline 2\\\hline \end{array}\quad \begin{array}{|c|c|c|}\hline 1&2&3\\\hline 1&2&5\\\hline \end{array}\begin{array}{|c|c|}\hline 1&2\\\hline 2&3\\\hline \end{array}\begin{array}{|c|}\hline 5\\\hline 5\\\hline \end{array}\right) \qquad (**)$$

Neither the tableau $(*)$, nor the double tableau $(**)$ are standard, and thus we may use the quadratic relations on Plücker coordinates to "straighten" the tableau $(*)$, which induces a straightening of the double tableau $(**)$ to a standard bi-tableau. These quadratic relations can be seen as the shuffling relations coming from the definition of the Schur functors from the previous sections.

2.2. Standard Plücker Coordinates. We consider the Plücker coordinate standard if and only if the associated tableau is, i.e. the tableau is strickly increasing along rows, and nondecreasing along columns. In this example, the coordinate is not standard. We have a **straightening law** on the coordinates which is given by the definition of the Schur-functors and the relations among tableaux induced by the multilinear map defining them, i.e. the **shuffling relations**. One may also view the straightening law on standard bi-tableaux as a consequence of the quadratic relations on Plücker coordinates in the Grassmannian. If we take the perspective of double tableaux, we let the left tableau be the "row tableau", with indices $j \in [1,n]$ and the right tableau as the "column tableau" with indices $i \in [1, m+n]$. Each pair of rows gives a minor of the matrix X. We think of the space of one line tableau of size k as a vector space M_k, with basis $(j_k, ..., j_i | i_1, ..., i_k)$, so that if two indices on the right or left are equal, then the symbol is zero, and the symbols are alternating separately on the left and right. For any partition $\lambda := m_1 \geq m_2 \geq \cdots \geq m_r$, the tableaux of shape λ can be thought of as a tensor product $M_{m_1} \otimes M_{m_2} \otimes \cdots \otimes M_{m_r}$. Evaluating a formal tabeleau as a product of minors gives a nontrivial kernel, which is the space spanned by the shuffling relations, or equivalently the straightening law. The action of $\mathrm{GL}(E) \times \mathrm{GL}(F)$ on $K[X]$ induces an action by the two groups of diagonal matrices, and the content of a bi-tableau is a weight vector for the product of the two algebraic tori. In particular If $(A, B) = (a_i) \times (b_j) \in T(E) \times T(F)$ is an element of the product of the tori $T(E) \subset \mathrm{GL}(E)$ and $T(F) \subset \mathrm{GL}(F)$, then the weight is $(\prod_{i+1}^{n} a_i^{-k(i)}; \prod_{j=1}^{m+n} b_j^{h(j)})$. At this point we should comment that there is a well-known partial order on multi-tableaux.

CHAPTER 10

Varieties of Circular Complexes

1. Varieties of Complexes

Let us now move on to a classic example, that of the *varieties of complexes*. These are examples of orbit closures of quivers which have been studied by many authors at this point (see for example [], [], []....). Let $S = k[X^{(k)}_{i(k),j(k)}]$, where $X^{(k)}$ is the kth matrix representing d_k in the complex

$$V_n \xrightarrow{d_n} V_{n-1} \xrightarrow{d_{n-1}} \cdots \xrightarrow{d_2} V_1 \xrightarrow{d_1} V_0$$

Let I be the ideal generated by $\mathrm{rank}(X^{(k)}) \times \mathrm{rank}(X^{(k)})$ minors of each $X^{(k)}$, and by the equations given by $X^{(k+1)}X^{(k)} = 0$. Then $R = S/I$ is the coordinate ring of the parametrizing variety of complexes with the dimension vector $(\mathrm{Grd}(1), ..., \mathrm{Grd}(n))$ and rank sequence $r = (r(1), ..., r(n-1))$.

Theorem 1.1. *(cite DEP, DS, PW, and T) The coordinate ring of a sequence of k-vector spaces*

$$V_n \xrightarrow{d_n} V_{n-1} \xrightarrow{d_{n-1}} \cdots \xrightarrow{d_2} V_1 \xrightarrow{d_1} V_0$$

has a filtration by Schur functors

$$\begin{aligned}&\mathcal{G}\nabla\mathcal{S}\dagger\Updownarrow(V_1 \otimes V_2^* \oplus \cdots \oplus V_{n-1} \otimes V_n^*)\\ &= \bigoplus_{(\lambda(1),...,\lambda(n-1))} L_{\lambda(1)}V_1 \otimes L_{\lambda(1)}V_2^* \otimes \cdots \otimes L_{\lambda(n-1)}V_{n-1} \otimes L_{\lambda(n-1)}V_n^*\end{aligned}$$

where each $\lambda(i)$ has at most $\min\{\dim V_i, \dim V_{i+1}\}$ *columns. In the case that such a sequence is a complex of vector spaces DeConcini and Strickland show that the filtration is*

$$\begin{aligned}&\mathcal{G}\nabla\mathcal{S}\dagger\Updownarrow(V_1 \otimes V_2^* \oplus \cdots \oplus V(_{n-1}\otimes V_n^*)/I\\ &= \bigoplus_{(\lambda(1),...,\lambda(n-1))} L_{(\lambda(1))}V_1 \otimes L_{(\lambda(2),-\lambda(1))}V_2 \otimes \cdots \otimes L_{(\lambda(n-1),-\lambda(n-2))}V_{n-1} \otimes L_{(-\lambda(n-1))}V_n.\end{aligned}$$

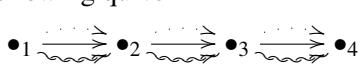
Here each $\lambda(k)$ has at most $\mathrm{rank}(d_k)$ *columns, where d_k are the differentials in the complex represented by the matrices $X^{(k)}$.*

Theorem 1.2. *(cite DEP, DS, PW, and T) The algebra R has a basis given by standard multitableaux. Further, the ring R is normal and Cohen-Macaulay.*

2. Products of Varieties of Complexes

We may of course take products of varieties of complexes. Such varieties arise naturally when there is a partition of a quiver into subquivers with relations of length two. Let us look at an example.

Example 2.1. Suppose Q is the following quiver



Let us denote the colors by the set $\{1,2,3\}$ (ordered from top to bottom). Let $\{a_1,a_2,a_3\}$ be the arrows of color "1", labeled from left to right. Similarly, label arrows of color "2" by $\{b_j\}_{j=1,2,3}$, and arrows of color "3" by $\{c_k\}_{k=1,2,3}$. Take the dimension vector $\mathrm{Grd}=(2,4,5,3)$, and rank maps $r_1=(2,2,3)=r_2, r_3=(1,3,2)$.

The associated graded object for the coordinate ring is

$$\begin{aligned} k[A_i,B_j,C_k]_{i,j,k=1,2,3}/I = {} & S_{(\lambda(a_1))}V_1\otimes S_{(\lambda(a_2),-\lambda(a_1))}V_2\otimes S_{(\lambda(a_3),-\lambda(a_2))}V_3\otimes S_{(-\lambda(a_3))}V_4 \\ & \otimes S_{(\mu(b_1))}V_1\otimes S_{(\mu(b_2),-\mu(b_1))}V_2\otimes S_{(\mu(b_3),-\mu(b_2))}V_3\otimes S_{(-\mu(b_3))}V_4 \\ & \otimes S_{(\nu(c_1))}V_1\otimes S_{(\nu(c_2),-\nu(c_1))}V_2\otimes S_{(\nu(c_3),-\nu(c_2))}V_3\otimes S_{(-\nu(c_3))}V_4. \end{aligned}$$

Using the dimension vector $(2,4,5,3)$ and the rank sequences $r_1=(2,2,3)=r_2$, and $r_3=(1,3,2)$, then the maps $\lambda,\mu,\nu : Q_1\to\mathcal{P}$, which assign a partition (or Young diagram) to each arrow, are restricted to partitions such that $\lambda(a_i)$ and $\mu(b_j)$ have no more than $r_1(i)=r_2(j)$ (for $i=j$) parts. Similarly, $\nu(c_k)$ is restricted to partitions which have no more than $r_3(k)$ parts.

Let $m_1=\langle 3|2\rangle_1^1\langle 2|2\rangle_1^1\langle 3|4\rangle_2^1\langle 2,3|2,4\rangle_3^1\in k[\mathrm{Grrep}_{Q,1}(\mathrm{Grd}_1,r_1)]$, $m_2=\langle 2|2\rangle_2^2\langle 1,2|1,2\rangle_3^2\in k[\mathrm{Grrep}_{Q,2}(\mathrm{Grd}_2,r_2)]$, and $m_3=\langle 2,3|2,3\rangle_2^3\langle 1,2|2,3\rangle_3^3\in k[\mathrm{Grrep}_{Q,3}(\mathrm{Grd}_3,r_3)]$. Then the monomial $m_1\otimes m_2\otimes m_3\in k[\mathrm{Grrep}_{Q,c}(\mathrm{Grd},r)]$ corresponds to the product of multitableaux,

$$\left(\emptyset,\ \begin{array}{|c|}\hline 2\\\hline 3\\\hline\end{array},\ \begin{array}{|c|c|c|}\hline 1&3&4\\\hline 1&3&4\\\hline 3\\\cline{1-1}\end{array},\ \begin{array}{|c|c|c|c|}\hline 1&2&3&5\\\hline 2&3\\\cline{1-2}\end{array},\ \begin{array}{|c|c|}\hline 1&3\\\hline\end{array}\right)\times\left(\emptyset,\ \begin{array}{|c|}\hline 2\\\hline\end{array},\ \begin{array}{|c|c|c|c|}\hline 1&3&4&5\\\hline 1&2\\\cline{1-2}\end{array},\ \begin{array}{|c|}\hline 3\\\hline\end{array}\right)\times\left(\emptyset,\ \begin{array}{|c|c|}\hline 2&3\\\hline\end{array},\ \begin{array}{|c|c|c|}\hline 1&4&5\\\hline 1&2\\\cline{1-2}\end{array},\ \begin{array}{|c|}\hline 1\\\hline\end{array}\right).$$

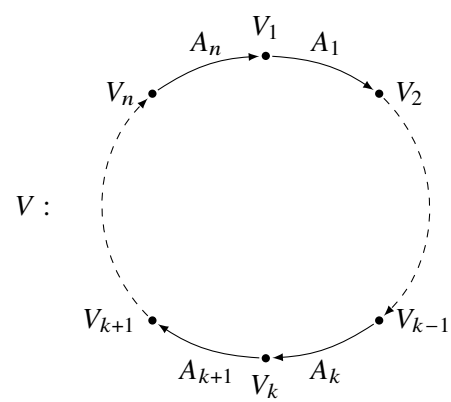
This is *not standard* since m_2 and m_3 are not standard, thus this is an element of $\Sigma(\mathrm{Grd})=\Sigma(\mathrm{Grd}_1)+\Sigma(\mathrm{Grd}_2)+\Sigma(\mathrm{Grd}_3)$. In the partial order induce by the block order[1], we have defined, it is larger than the monomial

$$\langle 3|2\rangle_1^1\langle 2|2\rangle_1^1\langle 3|4\rangle_2^1\langle 2,3|2,4\rangle_3^1\otimes\langle 2|3\rangle_2^2\langle 1,2|1,2\rangle_3^2\otimes\langle 2,3|2,3\rangle_2^3\langle 1,2|2,3\rangle_3^3,$$

which differs in only one place from the m_2 factor.

3. Varieties of Circular Complexes

Let $\Lambda_n=k\tilde{\mathbb{A}}_n/\mathrm{rad}(k\tilde{\mathbb{A}}_n)$ be the algebra given by taking the quotient of the hereditary algebra given by the equioriented type $\tilde{\mathbb{A}}$ quiver with $|Q_0|=|Q_1|=n$, by all paths of length two. Then any representation of Λ_n will be a circular complex of vector spaces $V\in\mathcal{C}_n(\mathrm{Grd},r)$,



[1]Let $k[x_1,...,x_k]$ have a monomial order $\leq_1$ and $k[x_{k+1},...,x_n]$ have a monomial order $\leq_2$. Then we define the **block order** on $k[x_1,...,x_k]\otimes k[x_{k+1},...,x_n]$ by saying for any pair of monomials $m,m'\in k[x_1,...,x_k]\otimes k[x_{k+1},...,x_n]$ that $m\leq m'$ if $x_1^{a_1}\cdots x_k^{a_k}\leq_1 x_1^{b_1}\cdots x^{b_k}$, or $x_1^{a_1}\cdots x_k^{a_k}=x_1^{b_1}\cdots x_k^{b_k}$, and $x_{k+1}^{a_{k+1}}\cdots x_n^{a_n}\leq_2 x_{k+1}^{b_{k+1}}\cdots x_n^{b_n}$.

where $\mathrm{Grd} = (\dim_k V_1, \dim_k V_2, ..., \dim_k V_n)$, so $\mathrm{Grd}(i) = \dim_k V_i$, and $r = (\mathrm{rank}\, A_1, \mathrm{rank}\, A_2, ..., \mathrm{rank}\, A_n)$ and $r(i) = \mathrm{rank}\, A_i$. It is easy to see that $r(i) + r(i+1) \leq \mathrm{Grd}(i+1)$ for $i \in \mathbb{Z}/n\mathbb{Z}$.

THEOREM 3.1. *Let $C_n(\mathrm{Grd}) = \mathrm{Grrep}(\Lambda_n, \mathrm{Grd})$ be the set of all representations of Λ_n with dimension vector* Grd*, and let $C_n(\mathrm{Grd}, r) = \mathrm{Grrep}(\Lambda_n, \mathrm{Grd}, r)$ be the subset of those representations with rank sequence r.*

$$C_n(\mathrm{Grd}) = \left\{ V \in \bigoplus_{i \in \mathbb{Z}/n\mathbb{Z}} \mathrm{Hom}(V(i), V(i+1)) \middle| V(a_{i+1})V(a_i) = A_{i+1}A_i = 0 \right\}$$

can be shown to have irreducible components given by rank sequence which are maximal with respect to Grd *with respect to the conditions $r(i) + r(i+1) \leq \mathrm{Grd}(i)$. Further, it is normal, Cohen-Macaulay, and has rational singularities. The equivariant filtration of the coordinate ring*

$$\mathbb{K}[C_n(\mathrm{Grd}, r)] = \bigoplus_{(\lambda_1, ..., \lambda_n)} \bigotimes_{i \in \mathbb{Z}/n\mathbb{Z}} S_{\lambda(i), -\lambda(i+1)} V(i)$$

holds.

PROOF. The proof proceeds in three steps.

Step 1. We establish the result for a three-term complex $F_2 \to F_1 \to F_0$ with single-row partitions $\lambda = (k)$ and $\mu = (l)$, reducing the Schur functor filtration to the kernel of the natural map $\bigwedge^k F_1^* \otimes \bigwedge^l F_1 \to S_{(l,-k)} F_1$. This is the content of the following lemma.

LEMMA 3.2. *For a three term sub-complex of a circular complex,*

$$F_2 \to F_1 \to F_0$$

with dimensions $\mathrm{Grd} = (\mathrm{Grd}(2), \mathrm{Grd}(1), \mathrm{Grd}(0))$ *and rank sequence $r = (r(2), r(1))$, for the map*

$$\phi : \bigwedge^k F_2 \otimes \bigwedge^k F_1^* \otimes \bigwedge^l F_1 \otimes \bigwedge^l F_0^* \to \bigwedge^k F_2 \otimes S_{(l,-k)} F_1 \otimes \bigwedge^l F_0^*,$$

we have that for $X = \ker \phi$, $I = R \cdot X = \mathcal{G}\nabla\mathcal{S}\dagger\Updownarrow(F_2 \otimes F_1^* \oplus F_1 \otimes F_0^*) \cdot X$ is exactly

$$R \cdot \left(\bigwedge^{r(2)+1} X^{(2)} \oplus \bigwedge^{r(1)+1} X^{(1)} \oplus F_2 \otimes F_0^* \right).$$

PROOF. Let $F_\bullet$ be the complex

$$F_2 \to F_1 \to F_0$$

the more general case for a complex of length n follows from this argument applied locally to each F_i, which we will elaborate on following the proof of the lemma. Let $\dim(F_i) = \mathrm{Grd}(i)$. Consider the case where $\lambda = (u)$, $\mu = (v)$ and take an element of

$$\bigwedge^u F_2 \otimes \bigwedge^u F_1^* \otimes \bigwedge^v F_1 \otimes \bigwedge^v F_0^*$$

of the form

$$e_{a_1} \wedge \cdots \wedge e_{a_u} \otimes f_{i_1}^* \wedge \cdots f_{i_u}^* \otimes f_{j_1} \wedge \cdots \wedge f_{j_v} \otimes g_{b_1}^* \wedge \cdots \wedge g_{b_v}^*.$$

Dualizing (i.e. tensoring with the determinant representation $\det(F_1)$) we may identify this with the element

$$e_{a_1} \wedge \cdots \wedge e_{a_u} \otimes f_{k_1} \wedge \cdots \wedge f_{k_{\mathrm{Grd}(1)-u}} \otimes f_{j_1} \wedge \cdots \wedge f_{j_v} \otimes g_{b_1}^* \wedge \cdots \wedge g_{b_v}^*$$

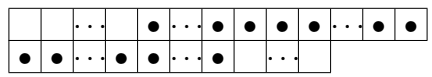
where $\{k_1, ..., k_{\mathrm{Grd}(1)-u}\}$ is the complement of $\{i_1, ..., i_u\}$ in $\{1, ..., \mathrm{Grd}(1)\}$. This element is in the space

$$\bigwedge^u F_2 \otimes \bigwedge^{\mathrm{Grd}(1)-u} F_1 \otimes \bigwedge^v F_1 \otimes \bigwedge^v F_0^*.$$

We may identify

$$f_{k_1} \wedge \cdots \wedge f_{k_{\mathrm{Grd}(1)-u}} \otimes f_{j_1} \wedge \cdots \wedge f_{j_v}$$

with the corresponding tableau, and identifying f_i with the positive integer $i \in \{1, ..., \mathrm{Grd}(1)\}$. We may assume such a tableau is standard, i.e the rows are strictly increasing and the columns are weakly increasing. The image of the tableau t can be computed using the diagram



with r empty boxes in the first row which is of length $\mathrm{Grd}(1) - u$, and s empty boxes in the second row which is of length v. This is a mnemonic device for computing the image of the following maps

$$\begin{array}{c} \bigwedge^r F_1 \otimes \bigwedge^{\mathrm{Grd}(1)-u-r+v-s} F_1 \otimes \bigwedge^v F_1 \\ \Big\downarrow {\scriptstyle 1\otimes\Delta\otimes 1} \\ \bigwedge^r F_1 \otimes \bigwedge^{\mathrm{Grd}(1)-u-r} F_1 \otimes \bigwedge^{v-s} F_1 \otimes \bigwedge^v F_1 \\ \Big\downarrow {\scriptstyle m_{12}\otimes m_{34}} \\ \bigwedge^{\mathrm{Grd}(1)-u} F_1 \otimes \bigwedge^v F_1 \end{array} .$$

The image of t is a sum of tableaux. Now let R be the first r entries of the first row (in the empty boxes), let Y be the remaining entries of the first row, Y' the first $v - s$ entries of the second row, and S the last s entries of the second row. Suppose that R, Y, Y', S are all disjoint sets. Then t maps to a sum of tableaux, say $t \mapsto \sum t'$, which we may identify with the corresponding tensor, and such that after dualizing $\bigwedge^{\mathrm{Grd}(1)-u} F_1 \otimes \bigwedge^v F_1 \to \bigwedge^u F_1^* \otimes \bigwedge^v F_1$, $\sum t' \mapsto (\sum t')^* \in \bigwedge^u F_1^* \otimes \bigwedge^v F_1$, the element

$$e_{a_1} \wedge \cdots \wedge e_{a_u} \otimes \left(\sum t'\right)^* \otimes g^*_{b_1} \wedge \cdots \wedge g^*_{b_v}$$

is an entry of □

Step 2. For general partitions λ and μ, the Schur functor relations are generated by straightening relations that act on pairs of adjacent rows. Since the straightening law for $S_\lambda F_1^* \otimes S_\mu F_1$ decomposes into operations on consecutive row pairs (λ_i, μ_j), each such pair reduces to the single-row case handled in Step 1. Concretely, the ideal of relations for the general Schur filtration is the sum of the ideals obtained by applying Step 1 to each pair of adjacent rows in the combined Young diagram.

Step 3. For a circular complex of length n (rather than 3), the computation localizes: at each term F_i one applies the three-term argument to the subcomplex $F_{i+1} \to F_i \to F_{i-1}$ (indices modulo n). The global ideal is therefore generated by the local contributions from each vertex of the circular complex. This completes the proof.

□

3.1. Hochster–Buchsbaum–Eisenbud multipliers and Grassmannians over rings ("Grass(R)"). The informal "missing link" in the preceding sketch is the *functorial* determinantal control of exactness and rank–strata *over an arbitrary commutative base ring* R, and not only over a field. This is precisely the viewpoint developed in §7 of Hochster's CBMS notes [65], building on the structure theorems of Buchsbaum–Eisenbud for finite free acyclic complexes [66]. We summarize the pieces we will actually use, emphasizing how they interface with the circular-complex/quiver picture.

3.1.1. *Complementary minors as Plücker coordinates.* Let K be a field, $V \cong K^t$, and let A be an $r \times t$ matrix over K with $\operatorname{rank}(A) = r$. Viewing the rows of A as a basis of an r-plane $V^r \subset V$, the maximal minors of A are the Grassmann–Plücker coordinates of V^r under the Plücker embedding

$$GrGr_r(V) \hookrightarrow \mathbb{P}\Big(\bigwedge^r V\Big).$$

If B is a $t \times s$ matrix with $s = t - r$ and $AB = 0$ and $\operatorname{rank}(B) = s$, then the columns of B span an s-plane which identifies canonically with an orthogonal complement to V^r in V^*. Hochster recalls the following classical "complementary minors" relation (a linear-algebra avatar of the isomorphism $GrGr_r(V) \cong GrGr_s(V^*)$): there is a unique scalar $c \in K^\times$ such that, for every r-subset $\mu \subset \{1, \dots, t\}$, the corresponding maximal minors satisfy

$$B_\mu \;=\; c\ \mathrm{Grsign}(\mu)\, A_\mu, \tag{3.1}$$

where $\mathrm{Grsign}(\mu)$ is an explicit sign depending on μ (Hochster chooses $\mathrm{Grsign}(\mu) = (-1)^{\Sigma/2}$ with Σ the sum of the elements of μ). See [65, §7] for the statement and its interpretation in terms of Plücker coordinates.

3.1.2. *Vectors of multipliers for long exact complexes.* Now let R be a commutative ring and let

$$0 \to V_n \xrightarrow{A_n} V_{n-1} \xrightarrow{A_{n-1}} \cdots \xrightarrow{A_2} V_1 \xrightarrow{A_1} V_0 \to 0 \tag{3.2}$$

be a finite free acyclic complex of R-modules with specified bases. Write $b_i = \operatorname{rank}_R(V_i)$ and let r_i denote the *expected rank* of A_i (so that, in the acyclic case, $b_i = r_i + r_{i+1}$ in the standard Buchsbaum–Eisenbud conventions). Hochster formulates a systematic refinement of (3.1): for each i there is a *vector of multipliers* $c^{(i)} = (c^{(i)}_\mu)$ indexed by suitable subsets μ, such that (up to the fixed sign conventions) vectors of maximal minors of A_i are obtained from vectors of maximal minors of A_{i+1} by multiplication with $c^{(i)}$. The existence and uniqueness of these multiplier vectors over a Noetherian ring are recorded in Hochster's Theorem 7.1 [65, §7], and can be viewed as the determinantal shadow of the exterior-algebra factorization in [66].

3.1.3. *Universal rings for resolutions of length two.* A crucial consequence is that for complexes of length 2 there exists a *universal pair* $(R, \mathcal{K})$ (classifying all acyclic complexes of a fixed Betti type (b_0, b_1, b_2) under base-change), and the universal ground ring R is an integrally closed finitely generated graded $\mathbb{Z}$-algebra; see Hochster's Theorem 7.2 [65, §7]. Kustin–Weyman [72] revisit this universal ring $\widetilde{C}$ and the universal resolution

$$U: \quad 0 \to \widetilde{C}^e \xrightarrow{d_2} \widetilde{C}^f \xrightarrow{d_1} \widetilde{C}^g,$$

prove that $\widetilde{C}$ is factorial (Bruns [67, 68]), identify generators (Huneke [69]), and compute the *minimal free resolution* of $\widetilde{C}$ by Weyman's geometric method [72, 71].

Remark 3.3 (Why this matters here). The surface/dessin and "necklace" invariant story developed elsewhere in this manuscript rests on the idea that *cycles control invariants*. The multiplier formalism above is the determinantal expression of the same principle: the *maximal minors* are Plücker coordinates (cycle-like wedge monomials), and the multipliers encode how one "propagates" these wedge-cycles through an exact complex. In the circular-complex/quiver regime, these multipliers become *cycle weights* attached to adjacent rank constraints and thus interface cleanly with (i) the necklace/cycle trace generators of invariants (Procesi–Le Bruyn–Lusztig), and (ii) the total-positivity/positive-Grassmannian technology (Postnikov; Arkani-Hamed et al.) already used later in this paper.

3.2. Weyman–Kustin geometric technique for varieties of complexes. We now record the *geometric package* that turns the Hochster/Buchsbaum–Eisenbud determinantal relations into the geometric properties asserted for varieties of (circular) complexes: normality, Cohen–Macaulayness, rational singularities, and the Schur-functor filtrations.

3.2.1. *Incidence desingularization and cohomology.* Fix a field K of characteristic 0 and finite-dimensional K-spaces E, F, G with $\dim(E) = e$, $\dim(F) = f$, $\dim(G) = g$. Set

$$X := \mathrm{Hom}_K(E, F) \times \mathrm{Hom}_K(F, G), \qquad A := K[X].$$

Let $r_1 = f - e$ and $r_0 = g - f + e$ (as in [72]), and let $Y \subset X$ be the subvariety cut out by the determinantal ideal enforcing $\mathrm{rank}(d_2) \le e$, $\mathrm{rank}(d_1) \le r_1$, and $d_1 d_2 = 0$. Kustin–Weyman consider the incidence variety

$$Z := \{(d_2, d_1, R) \in X \times GrGr(e{+}1, F) \ : \ \mathfrak{I}(d_2) \subseteq R \subseteq \mathrm{Ker}(d_1)\},$$

which maps properly to Y and is a desingularization in the generic rank range [72, §2]. Let Q be the tautological quotient bundle on $GrGr(e{+}1, F)$ and R the tautological subbundle. The key point of Weyman's method is that Z is the total space of a vector bundle over the Grassmannian, and one reduces statements about $K[Y]$ and its syzygies to vanishing and identification statements for cohomology of Schur functors of the bundles R, Q.

Concretely, in the setup of [72, §2] one defines vector bundles

$$\xi := E \otimes Q^* \ \oplus \ R \otimes G^*, \qquad \eta := E \otimes R^* \ \oplus \ Q \otimes G^*,$$

and proves (by Borel–Weil–Bott) that

$$H^i(GrGr(e{+}1, F), \mathcal{G}\nabla\mathcal{S}\dagger\Updownarrow^j(\eta)) = 0 \quad \text{for all } i > 0, \tag{3.3}$$

and

$$H^0(GrGr(e{+}1, F), \mathcal{G}\nabla\mathcal{S}\dagger\Updownarrow^j(\eta)) \cong (A/I)_j, \tag{3.4}$$

where I is the defining ideal of Y [72, Prop. 3]. The vanishing (3.3) implies that Y has rational singularities, hence is normal and Cohen–Macaulay. Moreover, the minimal free resolution of A/I as an A-module is computed from the cohomology of exterior powers $\bigwedge^q \xi$ [71, §1].

3.2.2. *Schur filtrations and standard monomials.* The Schur-functor decompositions appearing in (3.4) are a manifestation of the Cauchy identities and the Littlewood–Richardson rule applied to $\mathcal{G}\nabla\mathcal{S}\dagger\Updownarrow(\eta)$. In many instances (including the determinantal and complex varieties relevant here) these coordinate rings are *Hodge algebras* (algebras with straightening laws) in the sense of De Concini–Procesi and Bruns–Vetter; see [70, 67]. Consequently, one obtains a basis by *standard monomials*, which in the representation-theoretic language is exactly the "standard multitableaux" basis alluded to in the corollary following the circular-complex theorem.

3.3. Geometric completion for circular complexes. We now explain how the preceding Hochster–Weyman package supplies a complete proof of the claims stated at the beginning of this section for $C_n(\mathrm{Grd}, r)$, without changing any of the earlier exposition.

Proposition 3.4 (Incidence model for circular complexes). *Fix* $\mathrm{Grd} = (\mathrm{Grd}(1), \dots, \mathrm{Grd}(n))$ *and a rank sequence* $r = (r(1), \dots, r(n))$ *satisfying the circular rank inequalities* $r(i){+}r(i{+}1) \le \mathrm{Grd}(i{+}1)$ *(indices mod n). Let* $X := \prod_{i \in \mathbb{Z}/n\mathbb{Z}} \mathrm{Hom}_K(V(i), V(i{+}1))$ *and let* $Y \subset X$ *be the closed subvariety cut out by the relations* $A_{i+1}A_i = 0$ *and the rank conditions* $\mathrm{rank}(A_i) \le r(i)$. *Then there is a proper incidence variety*

$$Z := \{(A_\bullet, R_\bullet) \ : \ \mathfrak{I}(A_i) \subseteq R_i \subseteq \mathrm{Ker}(A_{i+1}), \ \dim R_i = r(i) + \delta_i\} \subset X \times \prod_i GrGr(r(i){+}\delta_i, V(i{+}1)),$$

for suitable choices of $\delta_i \in \{0, 1\}$ *in the generic rank range, such that the projection* $Z \to Y$ *is a desingularization on the open locus where the ranks are exactly* $r(i)$.

Proof sketch. This is the obvious cyclic analogue of the incidence construction in [72, §2]. For each adjacent pair $V(i) \xrightarrow{A_i} V(i{+}1) \xrightarrow{A_{i+1}} V(i{+}2)$ one inserts an intermediate subspace $R_i \subset V(i{+}1)$ satisfying

$\mathfrak{I}(A_i) \subseteq R_i \subseteq \mathrm{Ker}(A_{i+1})$. Taking the product over i yields Z as a closed subvariety of a product of Grassmannians ("Grass(R)" in Hochster's sense), and the map to Y is proper because the Grassmannians are proper. On the generic rank stratum, R_i is forced to equal $\mathrm{Ker}(A_{i+1})$ (or $\mathfrak{I}(A_i)$, depending on the chosen δ_i), giving birationality. □

Theorem 3.5 (Normality, Cohen–Macaulayness, rational singularities, and Schur filtration). *Over a field K of characteristic 0, each rank-maximal irreducible component $C_n(\mathrm{Grd}, r)$ of the variety of circular complexes is normal, Cohen–Macaulay, and has rational singularities. Moreover, its coordinate ring admits a $G_{\mathrm{Grd}} = \prod_i \mathrm{GL}(V(i))$-equivariant filtration whose associated graded decomposes as*

$$\mathbb{K}[C_n(\mathrm{Grd}, r)] \;\cong\; \bigoplus_{(\lambda_1,\dots,\lambda_n)} \bigotimes_{i\in\mathbb{Z}/n\mathbb{Z}} S_{\lambda(i),-\lambda(i+1)}V(i),$$

and in particular has a basis by standard multitableaux.

Idea of proof. Apply Weyman's geometric method componentwise on the product $\prod_i GrGr(\cdots)$ appearing in Proposition 3.4. Each incidence condition $\mathfrak{I}(A_i) \subseteq R_i \subseteq \mathrm{Ker}(A_{i+1})$ identifies the corresponding piece of Z as the total space of a vector bundle over a Grassmannian, with the same ξ/η-bundle formalism as in [72, 71]. The required cohomology vanishing for symmetric powers of the analogue of η follows from Borel–Weil–Bott. Consequently the pushforward of $\mathcal{O}_Z$ is $\mathcal{O}_Y$ with higher direct images 0, yielding rational singularities (hence normality and Cohen–Macaulayness). The Schur-functor decomposition and the standard multitableaux basis are obtained from the Cauchy identities and standard monomial theory for the resulting Hodge algebra; see [70, 67]. □

3.4. Face cycles as circular complexes and global gluing by fibre products. The Grass(R) and incidence constructions above explain the geometry of a *single* circular-complex locus $C_n(\mathrm{Grd}, r)$. In the surface/dessin setting, however, one meets many such loci simultaneously, one for each face of the dessin. It is therefore important to record explicitly *where* circular complexes live in the $(\sigma_0, \sigma_1, \sigma_\infty)$ formalism and how they assemble into the global representation varieties of surface algebras and surface orders.

Remark 3.6 (Circular complexes live on σ_∞–faces (anti-cycles), not on σ_0/σ_1 vertices). Recall (cf. the discussion around the "allowed/forbidden" successor permutations) that:

- σ_0 and σ_1 encode the *vertex cycles* (allowed continuations, not in the ideal I), and
- σ_∞ encodes the *face cycles*, which in the gentle surface-algebra regime are precisely the *anti-cycles* (cycles of zero-relations): consecutive arrows along a σ_∞–cycle compose to 0 in $\Lambda = kQ/I$.

Fix a face f with σ_∞–cycle of length $\ell(f)$, and write the corresponding oriented boundary arrows as

$$a_1 : a_1^- \to a_1^+,\ a_2 : a_2^- \to a_2^+,\ \dots,\ a_{\ell(f)} : a_{\ell(f)}^- \to a_{\ell(f)}^+, \qquad a_{i+1}a_i \in I,$$

(indices mod $\ell(f)$). For any representation ρ of Λ with vertex spaces $(V_v)_{v\in Q_0}$, the restricted data

$$A_i := \rho(a_i) \in \mathrm{Hom}(V_{a_i^-}, V_{a_i^+})$$

satisfy $A_{i+1}A_i = 0$ by the defining relations. Thus *each face determines a genuine circular complex*, and the corresponding face-locus is a variety of circular complexes in the sense of Proposition 3.4 and Theorem 3.5. In contrast, σ_0– and σ_1–cycles are the *allowed* directed cycles whose traces/necklaces generate the GL/SL invariant rings (Procesi–Le Bruyn–Lusztig), and they control *observables* rather than *relations*.

3.4.1. *From local face-loci to global surface representation varieties.* Let Γ be a (clean) dessin on a compact surface Σ, with face set $F(\Gamma)$ and associated gentle surface algebra/order $\Lambda = \Lambda(\Gamma)$. For each face $f \in F(\Gamma)$, let Q_f be the cyclic bound subquiver determined by the σ_∞–cycle of f (so Q_f is a cyclic quiver

of type $\widetilde{\mathbb{A}}_{\ell(f)}$ with radical-square-zero relations). Write $\mathrm{Comp}_f(\mathrm{Grd}_f, r_f)$ for the rank-bounded circular-complex locus on Q_f with the induced boundary dimension/rank data.

There are two equivalent bookkeeping viewpoints:

(a) (*Global-first.*) Fix the vertex vector spaces $(V_v)_{v\in Q_0}$ once and for all. Since every forbidden length-2 path lies on a unique σ_∞–face cycle, the defining equations of $\mathrm{GrRep}(\Lambda, \mathrm{Grd})$ are the union of the face-wise equations $A_{i+1}A_i = 0$ and the corresponding face-wise rank minors. Thus $\mathrm{GrRep}(\Lambda, \mathrm{Grd})$ is cut out by a *face-local* determinantal/quadratic ideal inside the ambient affine space $\prod_{a\in Q_1} \mathrm{Hom}(V_{t(a)}, V_{h(a)})$.

(b) (*Local-first (gluing).*) If one duplicates the boundary vertex spaces separately for each face f (i.e. works with a disjoint union of face-boundary complexes), then the naive product $\prod_{f\in F(\Gamma)} \mathrm{Comp}_f(\mathrm{Grd}_f, r_f)$ has "too many" copies of each vertex space. The genuine global representation variety is obtained by identifying the duplicated copies along shared incidences (half-edges), i.e. by imposing diagonal equalities on the duplicated boundary data. Scheme-theoretically this is an iterated *fibre product* (pullback) of affine schemes, matching the ring-theoretic "tensor / fibre-product dictionary" used earlier for orders; compare Definition 0.16.

In either viewpoint, the essential point for our later positivity/self-adjointness arguments is the same:

> *surface-algebra/order representation varieties are assembled from face-cycle circular-complex loci, and each such face-locus admits an incidence realization over a product of Grassmannians (Grass(R)).*

3.4.2. *Corrected roadmap: Grass(R) incidence $\Rightarrow$ positivity $\Rightarrow$ self-adjointness.* For quick reference, the logical dependency chain used throughout the manuscript can be summarized as the following corrected "face-cycle" roadmap:

(3.5)

§7 Hochster (Grass(R)): incidence for $(B \circ A = 0)$ and determinantal ranks

$\Longrightarrow$ σ_∞–face anti-cycles $\rightsquigarrow$ circular-complex loci $\mathrm{Comp}_f(\mathrm{Grd}_f, r_f)$ (iterated incidence over $\prod GrGr(\cdot)$)

$\Longrightarrow$ surface algebras/orders: $\mathrm{GrRep}(\Lambda(\Gamma), \mathrm{Grd})$ assembled by gluing (fibre products) of the face loci

$\Longrightarrow$ Magyar/Lusztig: cyclic-quiver loci $\hookrightarrow$ affine Schubert/affine Grassmannian models

$\Longrightarrow$ generalized minors / Plücker coordinates on Grassmannians

$\Longrightarrow$ positive Grassmannian charts (Postnikov; Arkani–Hamed et al.) and total nonnegativity/positivity of minors

$\Longrightarrow$ totally nonnegative/positive transfer matrices + cycle-reversal/detailed balance

$\Longrightarrow$ self-adjoint (symmetrized) modular/Hamiltonian generator (cf. Proposition 5.2).

We stress that the "vertex-cycle" (σ_0, σ_1) picture and the "face-cycle" (σ_∞) picture play *complementary* roles:

- face cycles (σ_∞) give the *relations* $A_{i+1}A_i = 0$, hence the determinantal/incidence geometry and the Hochster–Weyman package;
- vertex cycles (σ_0, σ_1) give the *cycle/necklace observables* generating GL/SL invariants, hence the natural positive coordinate functions whose positivity we propagate through the Grassmannian atlas.

3.5. Total positivity via the positive Grassmannian. Finally, we spell out why the Grassmannian/incidence realization is the appropriate setting for *total positivity*, and why this is compatible with the cycle/-necklace invariant picture.

- (*Plücker positivity.*) On the totally positive part $GrGr_k(n)_{>0}$, all Plücker coordinates (minors) are strictly positive. In such a chart, the Hochster multipliers in (3.1) become *positive* ratios of complementary minors, hence are positive functions.
- (*Subtraction-free parametrizations.*) Postnikov's network parametrizations and the cluster/positroid structure on $GrGr_k(n)$ provide subtraction-free coordinate charts on $GrGr_k(n)_{>0}$, ensuring that all Plücker coordinates (and therefore all determinantal semi-invariants built from them) are positive Laurent polynomials in positive variables [49, 50].
- (*From determinantal generators to cycle/necklace generators.*) In the quiver invariant setting, Procesi–Le Bruyn–Lusztig show that GL- and SL-invariants are generated by traces along oriented cycles ("necklaces"). Under the determinantal/Grassmannian incarnation of complexes, these traces are obtained from matrix coefficient functions built from minors and multipliers; hence positivity of minors implies positivity of cycle invariants on the corresponding positive loci.

This is the precise sense in which the Hochster–Weyman–Grassmann package upgrades "wiring diagram positivity" to a geometric positivity principle compatible with both the representation-theoretic filtration and the surface/dessin cycle calculus used elsewhere in this paper.

Corollary 3.7. *The acoordinate ring of a variety of circular complexes has a basis given by standard multitableaux. Further, the coordinate ring is normal and Cohen-Macaulay.*

4. Examples Calculations

Let us look at a few examples of the computations mentioned in the previous section.

Example 4.1. Let us consider the sequence

$$F_2 \xrightarrow{A} F_1 \xrightarrow{B} F_0$$

where the sequence of dimensions is $(3, 5, 3)$, $\operatorname{rank}(A) \leq 2$, and $\operatorname{rank}(B) \leq 3$. Then

$$R = \mathcal{G}\nabla\mathcal{S}\dagger\Updownarrow(F_2 \otimes F_1^* \otimes F_1 \otimes F_0^*)/I$$

where I is generated by $\bigwedge^3 F_2 \otimes \bigwedge^3 F_1^*$, and $F_2 \otimes F_0^*$. Suppose we take partitions $\lambda = (2)$ and $\mu = (1)$. Then we have the corresponding sequence of maps

$$\begin{array}{c} \bigwedge^4 F_1 \\ \downarrow \\ \bigwedge^2 F_2 \otimes \bigwedge^2 F_1^* \otimes F_1 \otimes F_0^* \\ \downarrow \\ \bigwedge^2 F_2 \otimes S_{(1,0,0,-1,-1)} F_1 \otimes F_3^* \end{array}$$

where $S_{(1,0,0,-1,-1)} F_1 \cong L_{(3,1)} F_1 \otimes \bigwedge^5 F_1^*$, and $\bigwedge^2 F_1 \otimes F_1^* \cong (\bigwedge^3 F_1 \otimes \bigwedge^5 F_1^*) \otimes F_1 \cong \bigwedge^3 F_1 \otimes F_1$ (in an $\mathrm{SL}(F_1)$-equivariant way). The map $\Delta : \bigwedge^4 F_1 \to \bigwedge^3 F_1 \otimes F_1$ is given by

$$f_{j_1} \wedge \cdots \wedge f_{j_4} \mapsto \sum_{\sigma \in S_4^{(3,1)}} \mathrm{Grsign}(\sigma) f_{\sigma(j_1)} \wedge f_{\sigma(j_2)} \wedge f_{\sigma(j_3)} \otimes f_{\sigma(j_4)}$$

The isomorphism $f_{\sigma(j_1)} \wedge f_{\sigma(j_2)} \wedge f_{\sigma(j_3)} \mapsto f^*_{j'_1(\sigma)} \wedge f^*_{j'_2(\sigma)}$ of $\bigwedge^3 F_1 \cong \bigwedge^2 F_1^*$, where $\{j'_1(\sigma), j'_2(\sigma)\}$ is the complement of $\{\sigma(j_1), \sigma(j_2), \sigma(j_3)\} \subset [1,5]$, then induces the map

$$\bigwedge^4 F_1 \to \bigwedge^2 F_1^* \otimes F_1$$

giving

$$f_{j_1} \wedge \cdots \wedge f_{j_4} \mapsto \sum_{\sigma \in S_4^{(3,1)}} \mathrm{Grsign}(\sigma) f^*_{j'_1(\sigma)} \wedge f^*_{j'_2(\sigma)} \otimes f_{\sigma(j_4)}$$

where we sum over all $\sigma \in S_4^{(3,1)}$ or equivalently over all the complements $\{j'_1(\sigma), j'_2(\sigma)\} = [1,5] - \{\sigma(j_1), \sigma(j_2), \sigma(j_3)\}$, one pair for each $\sigma \in S_4^{(3,1)}$. Fixing a, b, c, this then corresponds to an element

$$(e_a \wedge e_b) \otimes \sum_{\sigma \in S_4^{(3,1)}} \mathrm{Grsign}(\sigma) f^*_{j'_1(\sigma)} \wedge f^*_{j'_2(\sigma)} \otimes f_{\sigma(j_4)} \otimes g^*_c$$

which corresponds to matrix elements

$$\begin{aligned} &\sum_{\sigma \in S_4^{(3,1)}} \mathrm{Grsign}(\sigma)[(A_{j'_1(\sigma),b} A_{j'_2(\sigma),a} - A_{j'_1(\sigma),a} A_{j'_2(\sigma),b}) \cdot B_{b,\sigma(j_4)}] \\ = &\sum_{\sigma \in S_4^{(3,1)}} \mathrm{Grsign}(\sigma)[(BA)_{j'_1(\sigma),\sigma(j_4)} A_{j'_2(\sigma),a} - (BA)_{j'_2(\sigma),\sigma(j_4)} A_{j'_1(\sigma),a}]. \end{aligned}$$

which is in the ideal I generated by $F_2 \otimes F_0^*$ (and $\bigwedge^3 F_2 \otimes \bigwedge^3 F_1^*$).

Example 4.2. Let us now choose $\lambda = (2)$ and $\mu = (2)$. We have the following map,

$$\begin{array}{c} \bigwedge^2 F_2 \otimes \bigwedge^2 F_1^* \otimes \bigwedge^2 F_1 \otimes \bigwedge^2 F_0^* \ . \\ \downarrow \\ \bigwedge^2 F_2 \otimes S_{(1,1,0,-1,-1)} F_1 \otimes \bigwedge^2 F_0^* \end{array}$$

We compute the kernel via the following maps

(1) $\bigwedge^4 F_1 \otimes F_1 \to \bigwedge^3 F_1 \otimes \bigwedge^2 F_1$,
(2) $F_1 \otimes \bigwedge^4 F_1 \to \bigwedge^3 F_1 \otimes \bigwedge^2 F_1$,
(3) $\bigwedge^5 F_1 \to \bigwedge^3 \otimes \bigwedge^2 F_1$.

The first map is given by

$$f_{j_1} \wedge \cdots \wedge f_{j_4} \otimes f_k \mapsto \sum_{\sigma \in S_4^{(3,1)}} \mathrm{Grsign}(\sigma) f_{\sigma(j_1)} \wedge f_{\sigma(j_2)} \wedge f_{\sigma(j_3)} \otimes f_{\sigma(j_4)} \wedge f_k,$$

which corresponds to the element

$$\sum_{\sigma \in S_4^{(3,1)}} \mathrm{Grsign}(\sigma) f^*_{j'_1(\sigma)} \wedge f^*_{j'_2(\sigma)} \otimes f_{\sigma(j_4)} \wedge f_k.$$

Fixing a, b, c, d we get a corresponding element

$$(e_a \wedge e_b) \otimes \left(\sum_{\sigma \in S_4^{(3,1)}} \mathrm{Grsign}(\sigma) f^*_{j'_1(\sigma)} \wedge f^*_{j'_2(\sigma)} \otimes f_{\sigma(j_4)} \wedge f_k \right) \otimes (g^*_c \wedge g^*_d).$$

where we associate the complement $\{j_1'(\sigma,k), j_2'(\sigma,k)\}$ of $\{\sigma(j_1),\sigma(j_2),\sigma(j_3)\}$ in $[1,5]$ to each $\sigma \in S_4^{(3,1)}$, and sum over all such pairs (or equivalently over all σ). This gives us the corresponding element

$$\sum_{\sigma\in S_4^{(3,1)}} \mathrm{Grsign}(\sigma)(A_{j_1'(\sigma),a}A_{j_2'(\sigma),b} - A_{j_2'(\sigma),a}A_{j_1'(\sigma),b}) \cdot (B_{c,\sigma(j_4)}B_{d,k} - B_{c,k}B_{d,\sigma(j_4)})$$

which is an element of $(\bigwedge^2 B)\cdot(\bigwedge^2 A) = \bigwedge^2(BA) \in \bigwedge^2(F_2\otimes F_0^*)$, and thus in the ideal I. Similarly, the map $F_1 \otimes \bigwedge^4 F_1 \to \bigwedge^3 F_1 \otimes \bigwedge^2 F_1$ defined by

$$f_k \otimes f_{j_1}\wedge\cdots\wedge f_{j_4} \mapsto \sum_{\sigma\in S_4^{(2,2)}} \mathrm{Grsign}(\sigma) f_k \wedge f_{\sigma(j_1)} \wedge f_{\sigma(j_2)} \otimes f_{\sigma(j_3)} \wedge f_{\sigma(j_4)}$$

will give an element in $\bigwedge^2(F_2\otimes F_0^*)$, as will the map $\bigwedge^5 F_1 \to \bigwedge^3 F_1 \otimes \bigwedge^2 F_1$ given by

$$f_1\wedge\cdots\wedge f_5 \mapsto \sum_{\sigma\in S_5^{(3,2)}} \mathrm{Grsign}(\sigma) f_{\sigma(1)}\wedge f_{\sigma(2)}\wedge f_{\sigma(3)} \otimes f_{\sigma(4)}\wedge f_{\sigma(5)}.$$

Remark 4.3 (Coordinate rings via Grassmannians). The coordinate ring of a variety of complexes can be identified with a closed subring of a product of coordinate rings of Grassmannians. We develop this identification systematically in the next subsection, following Hochster's approach.

4.1. Grassmannian models over a commutative base ring: Hochster's $\mathrm{Grass}(R)$ **viewpoint for varieties of complexes.** The "variety of complexes" presentation above writes down equations directly in a polynomial ring $S = k[X^{(k)}_{i(k),j(k)}]$. For many purposes (base change, degeneration, positivity) it is better to keep track of *why* these are the right equations: they are *rank and incidence conditions* on submodules that are naturally parametrized by Grassmannians. This is the perspective taken systematically in Hochster's geometric treatment of determinantal loci and related exactness problems, and it is the reason the notation $\mathrm{Grass}(R)$ (Grassmannians over a commutative base ring R) is so effective [64, 63].

Grassmannians over a commutative ring. Fix a commutative ring R and integers $0 < r < n$. Let $GrGr_R(r,n)$ denote the Grassmannian over R representing the functor

$$S \longmapsto \left\{\text{rank-}r \text{ locally free direct summands } \mathcal{S} \subset S^n\right\}$$

on commutative R-algebras S. Equivalently, $GrGr_R(r,n)$ parametrizes rank-r quotients of S^n. It carries the universal exact sequence of vector bundles

$$0 \longrightarrow \mathcal{S} \longrightarrow \mathcal{O}_{GrGr}^{\oplus n} \longrightarrow \mathcal{Q} \longrightarrow 0, \tag{4.1}$$

whose formation commutes with base change in R. Plücker coordinates are global sections of $\bigwedge^r \mathcal{S}^\vee$ and furnish the standard closed immersion $GrGr_R(r,n) \hookrightarrow \mathbb{P}_R^{\binom{n}{r}-1}$.

Plücker/straightening relations as *defining relations*. Over any base ring, the homogeneous coordinate ring of $GrGr_R(r,n)$ is generated by Plücker variables p_I indexed by r-subsets $I \subset \{1,\dots,n\}$, with defining ideal generated by the quadratic Plücker relations. Standard monomial theory (in the form developed for Grassmannians and their Schubert subvarieties) provides:

(i) a monomial basis of the coordinate ring (standard monomials / standard tableaux),
(ii) explicit "straightening" relations expressing nonstandard monomials as R-linear combinations of standard ones, and
(iii) good singularity properties (normality, Cohen–Macaulayness) for many determinantal/rank loci, proved geometrically via Grassmannians.

Hochster–Eagon's principal radical system method is a foundational result in this direction: it shows that classical determinantal loci have Cohen–Macaulay and normal coordinate rings [63].

THEOREM 4.4 (Hochster–Eagon: generic determinantal loci are Cohen–Macaulay and normal). *Let R be a Noetherian ring and let X be a generic $m \times n$ matrix of indeterminates over R. Let $I_t(X)$ be the ideal generated by the $t \times t$ minors. Then the determinantal ring $R[X]/I_t(X)$ is Cohen–Macaulay, and in the domain case it is normal.*

REFERENCE. See [63] and the expository treatment in [64]. □

Varieties of complexes as incidence loci in products of Grassmannians. Now fix a complex of finite free R-modules (or vector spaces over a field)

$$F_n \xrightarrow{d_n} F_{n-1} \xrightarrow{d_{n-1}} \cdots \xrightarrow{d_2} F_1 \xrightarrow{d_1} F_0, \qquad d_{i-1} \circ d_i = 0,$$

and fix a rank sequence $Grr = (r_1, \ldots, r_n)$ with $0 \le r_i \le \min\{\operatorname{rk} F_i, \operatorname{rk} F_{i-1}\}$. Set $f_i := \operatorname{rk} F_i$. For each i we have:

$$\operatorname{im}(d_i) \subseteq F_{i-1} \text{ has rank } r_i, \qquad \ker(d_i) \subseteq F_i \text{ has rank } f_i - r_i.$$

The condition $d_{i-1} \circ d_i = 0$ is equivalent to the *incidence* condition

$$\operatorname{im}(d_i) \subseteq \ker(d_{i-1}) \subseteq F_{i-1} \qquad (2 \le i \le n). \tag{4.2}$$

Introduce the incidence scheme

$$\mathcal{I}(Grr) := \Big\{(I_1, K_1, \ldots, I_n, K_n) \ : \ I_i \in GrGr_R(r_i, F_{i-1}),\ K_i \in GrGr_R(f_i - r_i, F_i),\ I_i \subseteq K_{i-1}\Big\}, \tag{4.3}$$

where $K_0 := F_0$ and the inclusions are interpreted via base change of the universal sequences (4.1). Then the space of complexes with rank sequence Grr is (the image of) a natural morphism from $\mathcal{I}(Grr)$ to the affine space of differentials $\prod_i \operatorname{Hom}_R(F_i, F_{i-1})$: one recovers d_i as the composite

$$F_i \twoheadrightarrow F_i/K_i \xrightarrow{\tilde{d}_i} I_i \hookrightarrow F_{i-1},$$

where $\tilde{d}_i$ is an isomorphism once ranks are fixed appropriately (on a Stiefel open chart). In particular, the *equations* defining the variety of complexes are:

(a) determinantal rank conditions (vanishing of $(r_i + 1) \times (r_i + 1)$ minors of each d_i), and
(b) incidence equations enforcing (4.2), which are bilinear equations equivalent to $d_{i-1}d_i = 0$.

This is precisely the "Grassmannian technique" viewpoint: relations among minors are inherited from Plücker relations on the Grassmannians and their Schubert/incidence subvarieties, and base change is automatic.

REMARK 4.5 (Exactness and determinantal grade conditions). Over a Noetherian ring, exactness of a complex of free modules is controlled by determinantal/Fitting ideals (Buchsbaum–Eisenbud exactness criterion). Hochster's exposition emphasizes how these determinantal conditions can be interpreted geometrically on Grassmannians and how this geometric viewpoint interacts well with generic perfection and Cohen–Macaulayness [64]. In our context, this matters because "exactness" constraints on persistence complexes and "rank" constraints on circular complexes are both determinantal conditions of exactly this type.

4.1.1. *Why positivity follows: positive Grassmannians as a canonical sign atlas.* The positive/totally nonnegative Grassmannian $GrGr_{\ge 0}(r, n)$ (Section 1.3) is defined by the inequalities $p_I \ge 0$ on Plücker coordinates. There are two complementary reasons this is the correct positivity notion for our determinantal program.

(1) Subtraction-free coordinates and nonnegativity of minors. Postnikov's boundary measurement parametrizes cells of $GrGr_{\ge 0}(r, n)$ by planar networks with *positive* edge weights, and expresses each

Plücker coordinate as a subtraction-free sum over nonintersecting path families (Theorem 1.6). Therefore, whenever a determinantal semi-invariant or rank condition can be represented as a Plücker coordinate (or a minor of a boundary-measurement matrix), it is *automatically nonnegative* on the positive locus. This is the conceptual reason the Lindström–Gessel–Viennot lemma and wiring diagrams produce total nonnegativity: they are the matrix shadows of $GrGr_{\geq 0}$.

(2) Straightening with nonnegative structure constants. Standard monomial theory gives straightening relations of the form

$$p_I p_J = \sum_{(I',J')} c_{I,J}^{I',J'} \, p_{I'} p_{J'}$$

with coefficients $c_{I,J}^{I',J'} \in \mathbb{Z}$ determined by the Plücker relations. On the totally nonnegative locus, every $p_I \geq 0$, hence every straightening step preserves nonnegativity *provided the chosen atlas avoids sign cancellations*. Postnikov's network atlas does exactly this: in each cell, Plücker coordinates are subtraction-free in the network edge parameters, so the coefficients effectively contribute with the correct sign. In the toric degeneration limits used earlier (Section 4.4), each Plücker coordinate degenerates to its distinguished leading monomial, and the straightening relations become binomial relations in a semigroup algebra—again with canonical positive coefficients.

Corollary 4.6 (Determinantal loci inherit positivity from $GrGr_{\geq 0}$). *Any closed subscheme cut out by Plücker/determinantal equations inside a product of Grassmannians inherits a canonical "positive part" by intersecting with the corresponding product of totally nonnegative Grassmannians. On this positive part:*

(i) all minors defining rank conditions are nonnegative,

(ii) all LGV/network realizations evaluate determinantal semi-invariants as nonnegative sums over nonintersecting families, and

(iii) transfer matrices built from these minors are totally nonnegative (and totally positive on the interior), so the Gantmacher–Krein spectral conclusions apply (Theorem 1.2).

Remark 4.7 (Where this feeds the rest of the manuscript). The purpose of importing Hochster's Grass(R) viewpoint is not only commutative algebra. It also provides the clean geometric interface needed for:

(a) **Base change across arithmetic completions:** the Grassmannian functoriality of (4.1) matches the diagonal GL(Grd) $\hookrightarrow$ GL(n) embedding and the "local order" computations in the Artin L–function section.

(b) **Determinantal semi-invariants as Plücker coordinates:** Schofield/Derksen–Weyman determinants and Shmelkin's bidirected-walk generators are Plücker-type minors in disguise, hence live naturally on Grassmannians.

(c) **Positivity as a structural axiom:** positivity is not a post hoc inequality; it is the choice of atlas (positive Grassmannian/network charts) in which determinantal coordinates are subtraction-free, making total positivity compatible with toric degeneration and self-adjoint transfer operators.

CHAPTER 11

Representation Varieties of Compact Gentle Surface Algebras

1. Representation Varieties

Suppose we have a constellation $C = [\sigma, \alpha, \phi]$ and that Q is the associated medial quiver, and $\Lambda = \mathbb{K}Q/I$ is the corresponding surface algebra. We already know we may partition the arrows Q_1, in two useful ways, either with respect to ϕ, or with respect to σ. Let us use the partition of Q_1 in terms of ϕ. Denote by ϕ_i the ith cycle of ϕ and let $Q(\phi_i)$ be the corresponding subquiver of Q. Such a subquiver is a (not necessarily simple) cycle in Q. Further, the arrow set of each $Q(\phi_i)$ lies in the ideal of λ. In particular, composition of two consecutive arrows of $Q(\phi_i)$ is in the ideal. Let $\Lambda_i = kQ(\phi_i)/I$, where I is the ideal of Λ restricted to $Q(\phi_i)$.

Theorem 1.1. *Let* Grd *be a dimension vector for* Λ. *Let* $\mathrm{Grrep}(\Lambda_i, \mathrm{Grd}_i)$ *be the representation variety of* Λ_i *corresponding to the dimension vector* Grd_i, *which is the restriction of* Grd *to* $Q(\phi_i)$. *Then,*

$$\mathrm{Grrep}(\Lambda_i, \mathrm{Grd}_i) \cong C_i(\mathrm{Grd}_i)$$
$$= \left\{ V \in \bigoplus_{x \in \mathbb{Z}/n_i\mathbb{Z}} \mathrm{Hom}(V(x), V(x+1)) \middle| V(a_{i+1})V(a_i) = A_{i+1}A_i = 0 \right\}$$

is isomorphic to a variety of circular complexes, where $n_i = |\phi_i|$. *Therefore,*

$$\mathrm{Grrep}(\Lambda, \mathrm{Grd}) = \prod_{\phi_i} \mathrm{Grrep}(\Lambda_i, \mathrm{Grd}_i)$$

must be isomorphic to a product of such varieties.

Corollary 1.2. *We may thus describe the irreducible components in terms of the varieties of circular complexes. Let* $r : Q_1 \to \mathbb{N}$ *be a* ***rank map****, i.e. a function such that for every* ϕ_i, $r_i : Q(\phi_i)_1 \to \mathbb{N}$ *is a rank map for the dimension vector* Grd_i. *If* r_i *is maximal with respect to the dimension vector* Grd_i *for each i, then r gives an irreducible component of* $\mathrm{Grrep}(\Lambda, \mathrm{Grd})$, *which will be indexed by the rank map r, and denoted*

$$\mathrm{Grrep}(\Lambda, \mathrm{Grd}, r)$$

All irreducible components are obtained in this way.

.

2. Filtrations and Associated Graded Algebras

In this section we will describe the coordinate rings of the spaces $\mathrm{Grrep}(\Lambda, \mathrm{Grd})$, as well as the initial ideals of the defining ideals. We will also describe a standard monomial theory on the coordinate rings, and we will construct the associated graded algebra of the coordinate ring with respect to an equivariant filtration by Schur functors.

Theorem 2.1. *The varieties* $\mathrm{Spec}\,(\mathfrak{R}(\Lambda, \mathrm{Grd}, r))$ *for compact gentle surface algebras* Λ, *are Cohen-Macaulay, normal, and in fact have rational singularities.*

Proof. Suppose Q/I is the quiver with relations corresponding to the compact gentle surface algebra Λ. Let $\mathfrak{R} = \mathbb{K}[\mathrm{Grrep}(\Lambda, \mathrm{Grd}, r)]$ be the coordinate ring of some parametrizing variety for some dimension vector $\mathrm{Grd} \in \mathbb{N}^{Q_0}$, and let $\mathfrak{R}_i$ be the coordinate ring of the representation variety $\mathrm{Grrep}(\Lambda_i, \mathrm{Grd}_i, r_i)$. Suppose r is maximal with respect to Grd. Then each r_i is maximal with respect to Grd_i on $Q(\phi_i)$. Indeed, the restrictions on the ranks for varieties of circular complexes come from the length 2 relations on a circular complex, and thus the maximality conditions on r_i do not effect the maximality conditions on any other r_j for $i \neq j$. We may write

$$\mathfrak{R} = \bigotimes_{\phi_i} \mathfrak{R}_i$$

It follows that as a product of varieties of circular complexes, the variety $\mathrm{Spec}(\mathfrak{R})$ must be Cohen-Macaulay and normal. □

Proposition 2.2. *For an irreducible component of* $\mathrm{Grrep}(\Lambda, \mathrm{Grd}, r)$*, we have the following associated graded algebra for the coordinate ring* $\mathfrak{R} = \mathfrak{R}(\Lambda, \mathrm{Grd}, r) = \mathbb{K}[\mathrm{Grrep}(\Lambda, \mathrm{Grd}, r)]$*:*

$$\bigoplus_{\lambda: Q_1 \to \mathcal{P}} \left(\bigotimes_{\phi_i} \left(\bigotimes_{\substack{x = h(\phi_i^\ell a) \in Q(\phi_i)_0 \\ \ell \in \mathbb{Z}/n_i\mathbb{Z}}} S_{\lambda(\phi_i^\ell a), -\lambda(\phi_i^{\ell+1} \cdot a)} V(x) \right) \right)$$

where $ha = x = t(\phi_i \cdot a)$*, and* $\phi_i \cdot a$ *denotes the action of* ϕ_i *on* $Q(\phi_i)_1$*.* [1]

[1]Recall: ϕ_i corresponds to an *anti-cycle* in Q, i.e. a cycle of zero relations. We define an action of ϕ_i on the arrows of this anti-cycle $Q(\phi_i)_1$, simply by defining $\phi_i \cdot a$ to be the "next" arrow in the anti-cycle, for any arrow a. This just corresponds to the cyclic order of the boundary edges of the faces of $C = [\sigma, \alpha, \phi]$.

Proof. This follows from the definitions and combinatorics we have setup for the constellations $C = [\sigma, \alpha, \phi]$, their corresponding medial quivers, and compact gentle surface algebras.[2] For clarity, we list the necessary information:

(1) First, we setup a bijection between compact gentle surface algebras Λ and constellations C.
(2) We then defined a partition of the corresponding gentle quiver Q, via the anti-cycles ϕ_i corresponding to the faces of the cellularly embedded graph $\Gamma \hookrightarrow \Sigma$.
(3) Next, we described the representation varieties and coordinate rings of circular complexes and showed that the representation varieties of the subquivers $Q(\phi_i)$ under the partition by anti-cycles we isomorphic to varieties of circular complexes.
(4) Finally, we observed that the representation variety $\mathrm{Grrep}(\Lambda, \mathrm{Grd})$ is a product of such varieties of circular complexes and inherits their geometric properties.

□

Remark 2.3 (Moduli spaces, normality, and circular-complex factorization). The "anti-cycle factorization" of representation varieties into products of varieties of circular complexes is precisely the geometric input that makes invariant-theoretic moduli spaces tractable for gentle/special-biserial algebras. Concretely, for a special biserial algebra A the irreducible components of the GIT moduli spaces of θ–semistable representations are shown to be *products of projective spaces*; the proof strategy reduces normality and decomposition questions for $\mathrm{Grrep}(A, \mathrm{Grd})$ to the corresponding questions for products of varieties of circular complexes. This is exactly the structure exploited above: the face anti-cycles ϕ_i isolate the circular-complex factors $Q(\phi_i)$, and maximality of the rank map r identifies the "regular" components where the coordinate rings are Cohen–Macaulay and normal. Beyond being aesthetically pleasant, this matters later when gluing phases and clock holonomies are treated as learnable parameters: a moduli space with controlled geometry (products of projective spaces rather than arbitrary singular projective varieties) is a much safer domain for persistence-based inference and for operator-algebraic completion. See [38] for the special-biserial moduli-space theorem and the circular-complex reduction.

3. Standard Monomial Theory for the Coordinate Rings

Now, let us define the block order[3] on the monomials of $\mathfrak{R}$, i.e. with respect to the orders $\leq_i$ on each $\mathfrak{R}_i$ defined in §2.1 and 2.2.[4] We would like to describe a Gröbner basis for each $\mathfrak{R}_i$ and for $\mathfrak{R}$, via the standard monomials. In so doing we will show the following

Proposition 3.1. *The coordinate ring $\mathfrak{R}$ of the parametrizing varieties of representations of a compact gentle surface algebra Λ has a standard monomial theory.*

[2]In particular we showed that every gentle algebra that came from a finite 2-regular quiver. We called a quiver Q "2-regular" if every vertex had in-degree and out-degree exactly 2. We showed every such quiver had a unique constellation $C(Q) = [\sigma, \alpha, \phi]$, and therefore a unique graph Γ cellularly embedded in a closed Riemann surface Σ. We also showed that all constellations $C = [\sigma, \alpha, \phi]$ have a unique medial quiver, up to a choice of orientation of the surface, which is 2-regular, and that assigning length two relations to cycles in the quiver around a face of $\Gamma \hookrightarrow \Sigma$, and that this correspondence produces a bijection between constellations and (finite) gentle 2-regular quivers, and therefore also between constellations and compact gentle surface algebras.

[3]Let $k[x_1, ..., x_k]$ have a monomial order $\leq_1$ and $k[x_{k+1}, ..., x_n]$ have a monomial order $\leq_2$. Then we define the **block order** on $k[x_1, ..., x_k] \otimes k[x_{k+1}, ..., x_n]$ by saying for any pair of monomials $m, m' \in k[x_1, ..., x_k] \otimes k[x_{k+1}, ..., x_n]$ that $m \leq m'$ if $x_1^{a_1} \cdots x_k^{a_k} \leq_1 x_1^{b_1} \cdots x^{b_k}$, or $x_1^{a_1} \cdots x_k^{a_k} = x_1^{b_1} \cdots x_k^{b_k}$, and $x_{k+1}^{a_{k+1}} \cdots x_n^{a_n} \leq_2 x_{k+1}^{b_{k+1}} \cdots x_n^{b_n}$.

[4]Remember, it is arbitrary as to how one chooses to order the the components $\mathfrak{R}_i$ in relation to each other.

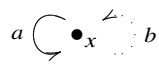
CHAPTER 12

Examples of Filtrations via Schur Functors and Associated Graded Algebras

1. Associated Graded Algebras of the Double Simple Cycle Algebras

2. Associated Graded Algebras for Compact Gentle Surface Algebras with One Simple Modules

2.1. The Dihedral Ringel Algebra $A_{1,1}$. Let $A_{1,1}$ be the algebra given by the following quiver with relations: $R = \langle a^2, b^2 \rangle$.



A representation for this algebra is a choice of two square matrices (A, B) with $A^2 = 0 = B^2$. The finite dimensional indecomposable representations correspond to words in the generators $\{a, b, a^{-1}, b^{-1}\}$ which do not pass through any zero relations. These are exactly the *string* and *band* modules. The description of the representation theory of infinite dimensional string algebras such as this one can be found in [58]. The coordinate ring of the parametrizing variety for the representations is $k[\mathrm{Grrep}(Q/R, \mathrm{Grd}(x))] = k[A, B]/I$, where I is the ideal generated by the equations $A^2 = 0 = B^2$. The irreducible component is unique and corresponds to the maximal rank pairs $r = (r(A), r(B))$ such that $2 \cdot r(A) \leq \mathrm{Grd}(x)$ and $2 \cdot r(B) \leq \mathrm{Grd}(x)$, where $\mathrm{Grd}(x) = \dim V(x)$ is the dimension of the vector space assigned to the vertex x, and r is maximal in the sense that increasing the rank of either A or B would not allow the relations $A^2 = 0 = B^2$ to be satisfied. The associated graded object for the coordinate ring is,

$$\mathrm{GrGr}(k[\mathrm{Grrep}(Q/R, \mathrm{Grd}(x), r)]) = \bigoplus_{\lambda} \left(S_{(\lambda(a), -\lambda(a))} V(x) \otimes S_{(\lambda(b), -\lambda(b))} V(x) \right),$$

where the sum is over all functions $\lambda : Q_1 \to \mathcal{P}$ assigning a partition $\lambda(a_i)$ to each arrow in $a_i \in Q_1$ such that each row is no longer than $r(a_i)$.

For this algebra we have the associated graded object for the ring of semi-invariants for a dimension $\mathrm{Grd}(x)$ and rank vector $r = (r(a), r(b))$,

$$\mathrm{GrGr}(\mathcal{SI}(Q/R, \mathrm{Grd}(x), r)) = \bigoplus_{\lambda} \left(S_{(\lambda(a), -\lambda(a))} V(x) \otimes S_{(\lambda(b), -\lambda(b))} V(x) \right)^{\mathrm{SL}(V(x))}.$$

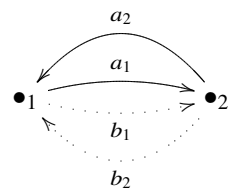
2.2. Gel'fand and Ponomarev's Algebra $A_{1,2}$. Let $A_{1,2}$ be given by the following quiver with relations: $R = \langle ab, ba \rangle$.

The associated graded object for the ring of semi-invariants for a given dimension $\mathrm{Grd}(x)$ and rank vector $r = (r(a), r(b))$ is:

$$\mathrm{GrGr}(\mathcal{SI}(Q/R, \mathrm{Grd}(x), r)) = \bigoplus_{\lambda} \left(S_{(\lambda(a), -\lambda(b))} V(x) \otimes S_{(\lambda(b), -\lambda(a))} V(x) \right)^{\mathrm{SL}(V(x))}.$$

3. Associated Graded Algebras for Compact Gentle Surface Algebras with Two Simple Modules

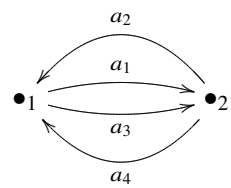
3.1. Algebra $A_{2,1}$. Let Q be the following quiver, and let the relations be $R = \langle a_2 a_1, a_1 a_2, b_2 b_1, b_1 b_2 \rangle$.



and denote this algebra $kQ/R = A_{2,1}$. We have the associated graded object for the ring of semi-invariants $\mathrm{GrGr}\,(\mathcal{SI}(Q/R, \mathrm{Grd}))$ is:

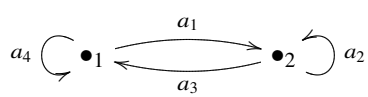
$$\bigoplus_{\lambda} \left(S_{(\lambda(a_1),-\lambda(a_2))}V(1) \otimes S_{(\lambda(b_1),-\lambda(b_2))}V(1)\right)^{\mathrm{SL}(V(1))} \otimes \left(S_{(\lambda(a_2),-\lambda(a_1))}V(2) \otimes S_{(\lambda(b_2),-\lambda(b_1))}V(2)\right)^{\mathrm{SL}(V(2))}.$$

3.2. Algebra $A_{2,2}$. $R = \langle a_2a_1, a_3a_2, a_4a_3, a_1a_4\rangle$.



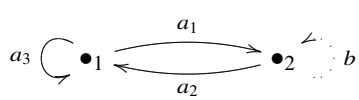
$$\bigoplus_{\lambda} \left(S_{(\lambda(a_1),-\lambda(a_4))}V(1) \otimes S_{(\lambda(a_3),-\lambda(a_2))}V(1)\right)^{\mathrm{SL}(V(1))} \otimes \left(S_{(\lambda(a_2),-\lambda(a_1))}V(2) \otimes S_{(\lambda(a_4),-\lambda(a_3))}V(2)\right)^{\mathrm{SL}(V(2))}.$$

3.3. Algebra $A_{2,3}$. $R = \langle a_2a_1, a_3a_2, a_4a_3, a_1a_4\rangle$.



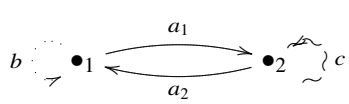
$$\bigoplus_{\lambda} \left(S_{(\lambda(a_1),-\lambda(a_4))}V(1) \otimes S_{(\lambda(a_4),-\lambda(a_3))}V(1)\right)^{\mathrm{SL}(V(1))} \otimes \left(S_{(\lambda(a_2),-\lambda(a_1))}V(2) \otimes S_{(\lambda(a_3),-\lambda(a_2))}V(2)\right)^{\mathrm{SL}(V(2))}.$$

3.4. Algebra $A_{2,4}$. $R = \langle a_2a_1, a_3a_2, a_1a_3, b^2\rangle$.



$$\bigoplus_{\lambda} \left(S_{(\lambda(a_1),-\lambda(a_3))}V(1) \otimes S_{(\lambda(a_3),-\lambda(a_2))}V(1)\right)^{\mathrm{SL}(V(1))} \otimes \left(S_{(\lambda(b),-\lambda(b))}V(2) \otimes S_{(\lambda(a_2),-\lambda(a_1))}V(2)\right)^{\mathrm{SL}(V(2))}.$$

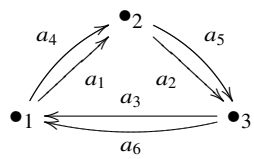
3.5. Algebra $A_{2,5}$. $R = \langle a_2a_1, a_1a_2, b^2, c^2\rangle$.



$$\bigoplus_{\lambda} \left(S_{(\lambda(a_1),-\lambda(a_2))}V(1) \otimes S_{(\lambda(b),-\lambda(b))}V(1)\right)^{\mathrm{SL}(V(1))} \otimes \left(S_{(\lambda(a_2),-\lambda(a_1))}V(2) \otimes S_{(\lambda(c),-\lambda(c))}V(2)\right)^{\mathrm{SL}(V(2))}.$$

4. Associated Graded Algebras for Compact Gentle Surface Algebras with Three Simple Modules

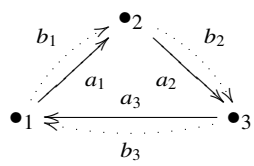
4.1. Algebra $A_{3,1}$.



$$\mathcal{SI}(Q/R, \mathrm{Grd}) = \bigoplus_{\lambda} \bigotimes_{i \in \mathbb{Z}/6\mathbb{Z}} S_{(\lambda(a_{i+1}), -\lambda(a_i))} V(x(i))^{\mathrm{SL}(V(x(i)))}.$$

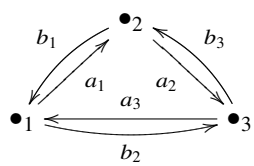
where $x(i) = ta_{i+1} = ha_i$, for each $i \in \mathbb{Z}/6\mathbb{Z}$.

4.2. Algebra $A_{3,2}$.

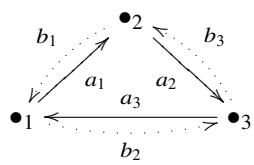


$$\mathcal{SI}(Q/R, \mathrm{Grd}) = \bigoplus_{\lambda} \left(\bigotimes_{i \in \mathbb{Z}/3\mathbb{Z}} S_{(\lambda(a_{i+1}), -\lambda(a_i))} V(i)^{\mathrm{SL}(V(i))} \right) \otimes \left(\bigotimes_{j \in \mathbb{Z}/3\mathbb{Z}} S_{(\lambda(b_{j+1}), -\lambda(b_j))} V(j)^{\mathrm{SL}(V(j))} \right).$$

4.3. Algebra $A_{3,3}$.



4.4. Algebra $A_{3,4}$.



Interestingly, the ring of semi-invariants for this algebra is isomorphic to the ring of semi-invariants of algebra $A_{3,2}$.

$$\mathcal{SI}(Q/R, \mathrm{Grd}) = \bigoplus_{\lambda} \left(\bigotimes_{i \in \mathbb{Z}/3\mathbb{Z}} S_{(\lambda(a_{i+1}), -\lambda(a_i))} V(i)^{\mathrm{SL}(V(i))} \right) \otimes \left(\bigotimes_{j \in \mathbb{Z}/3\mathbb{Z}} S_{(\lambda(b_{j+1}), -\lambda(b_j))} V(j)^{\mathrm{SL}(V(j))} \right).$$

CHAPTER 13

Spherical Varieties and Toric Degenerations

1. Shmelkin's Deformation Technique and Spherical Actions

In [1], Shmelkin develops a method of calculating invariant rings $k[\mathrm{Grrep}(\Lambda, \mathrm{Grd})]^{\mathrm{SL}(\mathrm{Grd})}$ in the coordinate ring of the parametrizing variety of representations for a class of (not necessarily finite dimensional) gentle algebras. The calculations of such rings for finite dimensional triangular gentle algebras was studied by Kraskiewics and Weyman[2], and later by Carroll and Weyman[3], and later the associated moduli spaces were studied by Carroll and Chindris[4]. Shmelkin's method provides an alternate method which is coordinate free, making some calculations simpler.

Let k be an algebraically closed field of characteristic zero, $G = (G, \mathcal{O}_G)$ a reductive group, and $X = (X, \mathcal{O}_X)$ an affine G-variety. The action of G is called **spherical** if for some point $x \in X$ and some Borel subgroup $B \leq G$, the orbit Bx is open and dense in X. A subgroup $H \leq G$ is spherical if the homogeneous variety $G/H = (G/H, \mathcal{O}_{G/H})$ is spherical. Here $\mathcal{O}_{G/H} = \pi_* \mathcal{O}_G^H$ is the direct image of the sheaf of H-invariant regular functions with respect to the projection $\pi : G \to G/H$ and the H action of right translations on G. By [47], X is spherical if and only if $k[X]$ is a multiplicity free G-module. Let $U \leq G$ me a maximal unipontent subgroup, and T a maximal torus normalizing U. Let χ_T be the **weights** of T, i.e. the group of all characters $\chi : T \to k$, and let χ_+ be the sub-semigroup of dominant weights with respect to B. For $\lambda \in \chi_+$, let V_λ be the corresponding simple module. Define $\Gamma(X)$ to be the set of highest weights of the G-irreducible factors of $k[X]$, with respect to T, for a G-variety X. $\Gamma(X)$ is a semigroup generated by the weights of the T-homogeneous generators of the algebra of covariants $k[X]^U$. In particular $\Gamma(G/H) = \{\lambda \in \chi_+ | \ V_\lambda^H \neq 0\}$. The G-variety X is then spherical if and only if $k[X]^U \cong k[\Gamma(X)]$. Now, X is normal and Cohen-Macaulay with rational singularities if and only if $\mathrm{Spec}(k[X]^U)$ is.

A sub-semigroup $\Gamma \leq \chi_+$ is **saturated** if the subgroup $\langle \Gamma \rangle \leq \chi_T$ has intersection with χ_+, $\langle \Gamma \rangle \cap \chi_+ = \Gamma$. For $\lambda \in \chi_+$ let $\langle v_\lambda \rangle \subset V_\lambda$ be the unique U-invriant line of highest weight vectors. For a sub-semigroup $\Gamma \leq \chi_+$ let

$$I(\Gamma) = \{g \in G | \ g v_\lambda = v_\lambda \ \forall \ \lambda \in \Gamma\}.$$

So, $U \subseteq I(\Gamma)$, and such U are called **horospherical**, and $I(\Gamma(G/H))$ is called the **horospherical contraction** of H. Next, we provide the setup that is important for our interests.

2. Highest Weight Modules

Let $G = \mathrm{GL}(V) \times \mathrm{GL}(V)$ and $H = \Delta\,\mathrm{GL}(V) \hookrightarrow G$ be the diagonal subgroup. Now, let $U \leq \mathrm{GL}(V) \cong H$ be the maximal unipotent subgroup of upper triangular matrices with 1's on the diagonal, and let $T \leq \mathrm{GL}(V)$

be the maximal torus of diagonal matrices. So, $B = UT$ is the Borel subgroup of upper triangular matrices. The characters χ_T are all of the form

$$\alpha_{ij}\begin{pmatrix} t_1 & 0 & \cdots & 0 \\ 0 & t_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & t_n \end{pmatrix} = t_i t_j^{-1}$$

and the weights of T in V are the characters $\chi \in \chi_T$ such that the weight spaces $V_\chi \subseteq V$,

$$V_\chi = \{v \in V |\ tv = \chi(t)v\ \forall\ t \in T\}$$

is nonzero. The vectors $v \in V_\chi$ are the weight vectors, and $V = \bigoplus_\chi V_\chi$. The root datum $\Psi = (\chi_T, R, \chi_T^*, R^*)$ where $\chi_T = \mathbb{Z}^n = \chi_T^*$, with pairing $\langle \chi, \chi^* \rangle = \chi(\chi^*(t)) = t^{\langle \chi, \chi^* \rangle}$ for $t \in k^*$. Further, $\alpha_{ij}^* : k^* \to \mathrm{GL}(V)$ with

$$\alpha_{ij}^*(t) = \begin{pmatrix} t_1 & 0 & \cdots & 0 \\ 0 & t_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & t_n \end{pmatrix}$$

where $t_i = t, t_j = t^{-1}$ and $t_k = 1$ for all $k \neq i, j$. We also have $R = R^* = \{e_i - e_j |\ i \neq j\}$ and the positive roots $R^+ = \{e_i - e_j |\ 1 \leq i < j \leq n-1\}$, with corresponding basis of simple roots $D = \{e_i - e_{i+1} |\ 1 \leq i < j \leq n-1\}$ for the Weyl group $W = S_n \cong N_G(T)/Z_G(T)$, where the centralizer of T is $Z_G(T) = T$ and the normalizer of T, $N_G(T)$ is the group of matrices with exactly one nonzero entry in each row and column. Clearly, modulo T, this is the group of permutation matrices given by the map $\rho : S_n \hookrightarrow \mathrm{GL}(V)$ where the generators $\sigma_i = (i, i+1) \mapsto \rho(\sigma_i)$ where $\rho(\sigma_i)e_i = e_{i+1}$, $\rho(\sigma_i)e_{i+1} = e_i$, and $\rho(\sigma_i)e_j = e_j$ for all $j \neq i, i+1$. Now, for brevity let $we_i = \rho(w)e_i$ for $w \in W$. Then W acts on the root system R. If $\alpha = \alpha_{ij} = e_i - e_j$ is a root, then $w = (i, j) = \sigma_\alpha$ is the reflection of R about the plane orthogonal to α_{ij}. Since $\sigma_\alpha = \sigma_i\sigma_{i+1}\cdots\sigma_{j-2}\sigma_{j-1}\sigma_{j-2}\cdots\sigma_{i+1}\sigma_i$ we have $W = \langle \sigma_i |\ 1 \leq i \leq n-1, \sigma_i^2 = 1 = (\sigma_i\sigma_{i+1})^3, \sigma_i\sigma_j = \sigma_j\sigma_i\ (i \neq j)\rangle$. Define the weight $\lambda^* := -w_0\lambda$, where w_0 is the longest element of the Weyl group.

Let $Y = G/B$ be the flag variety and $\pi : G \to Y$ the projection. Let $\mathcal{O}_Y$ be the sheaf of local rings on Y. Let $\mu \in \chi$ be a character (equiv. weight), $\mathcal{U}$ a Zariski open set in Y, and define a coherent sheaf $\mathscr{L}(\mu)$ of $\mathcal{O}_Y$-modules by,

$$\mathscr{L}(\mu)(\mathcal{U}) = \{f \in \mathcal{O}_G(\pi^{-1}\mathcal{U}) |\ f(xb) = f(xtu) = (w_0\mu)(t^{-1})(f(x)) = \chi_\mu(b)f(x)\}$$

here $(w_0\mu) = \chi_\mu \in \chi$, $x \in \pi^{-1}(\mathcal{U}), t \in T, u \in U$ (where $B = UT$ and U is the unipotent radical of the Borel subgroup B). The weight μ determines a $\mathrm{GL}(V)$-equivariant line bundle $\mathcal{L}(\mu)$ on Y, and there is a $\mathrm{GL}(V)$-action on the space of global sections $\Gamma(Y, \mathcal{L}_\mu) = H^0(Y, \mathcal{L}(\mu)) = L(\mu)$. If μ is a dominant weight then Bott's Theorem says this is an irreducible highest weight representation of $\mathrm{GL}(V)$. Further, all $H^i(Y, \mathcal{L}(\mu)) = 0$ for $i > 0$. In particular,

$$L(\mu) = \{f \in k[G] |\ f(xb) = \chi_\mu(b)f(x)\}$$

for $\chi_\mu \in \chi^+(B)$. All irreducible $\mathrm{GL}(V)$ modules can be obtained in this way.
Now, let B^{op} be the opposite Borel subgroup of lower triangular matrices. Let U^{op} be the unipotent radical of B^{op}. For any simple $\mathrm{GL}(V)$ module, the highest weight vector with respect to U^{op} is the lowest weight vector with respect to U with weight $-\mu^*$. Then let $\Gamma(G/H) = \{(\lambda, \lambda^*) \mid \lambda \in \chi_+(H)\}$, i.e. pairs of $\mathrm{GL}(V)$ dominant weights such that $V_\lambda \otimes V_{\lambda^*} = V_\lambda \otimes V_\lambda^*$ contains a $\mathrm{GL}(V)$ invariant point (V_λ an irreducible G-module of highest weight λ). Then $\Gamma(G/H)$ is saturated. So we then have,

$$I(\Gamma(G/H)) = (U \times U^{op})\Delta T$$

where $\Delta T = \{(t,t) \in T \times T\} \leq \mathrm{GL}(V) \times \mathrm{GL}(V)$. Now, let Z be some affine G-variety, $H = \Delta\,\mathrm{GL}(V)$ (a spherical subgroup).
Now, let $\leq$ be the partial order on weights in χ_T ($\lambda \leq \mu \iff \lambda - \mu$ is a nonnegative integer linear combination of simple roots). The highest weight λ is maximal in this order. This yields a partial order on irreducible factors of $k[Z]$ and $V_\lambda V_\mu$ is a sum of irreducible components smaller than or equal to $\lambda + \mu$ in the partial order. We then have the following

Proposition 2.1. [5] *An affine G-variety Z is spherical if and only if the G-module $k[Z]$ is multiplicity free. Further, if $H \leq G$ is a spherical subgroup, and V an irreducible G-module with* $\dim_k V < \infty$ *then* $\dim_k V^H \leq 1$.

Theorem 2.2. [6] *Let $H \leq G$ be a spherical subgroup of a connected reductive group G acting on the affine variety Z. Assume $\Gamma(G/H)$ is saturated. The associated graded algebra* $\mathrm{GrGr}\, k[Z]^H$ *given by the filtration $k[Z] = \bigcup_{\lambda \in \chi_+} k[Z]_{\leq \lambda}$ is isomorphic to $k[Z]^{I(\Gamma(G/H))}$.*

Now, let $Z = X \times Y$ be a product of affine $\mathrm{GL}(V)$-varieties and let $\mathrm{GL}(V)$ act diagonally (via restriction of the action of $G = \mathrm{GL}(V) \times \mathrm{GL}(V)$ to $H = \Delta\,\mathrm{GL}(V)$). By Theorem 2.4 of [7] we have

$$\mathrm{GrGr}\, k[Z]^{\Delta\,\mathrm{GL}(V)} \cong \left(k[X]^U \otimes k[Y]^{U^{op}}\right)^{\Delta T},$$

and

(1) If $k[Z]^{I(\Gamma(G/H))}$ is a complete intersection, then so is $k[Z]^H$.
(2) The number of generators in a minimal system of homogeneous generators of $k[Z]^{I(\Gamma(G/H))}$ is greater than or equal to that for $k[Z]^H$. In particular, if $k[Z]^{I(\Gamma(G/H))}$ is a polynomial ring, then so is $k[Z]^H$.

Now, let us assume Z is a spherical G-variety so that $k[Z] = \bigoplus_{\lambda \in \Gamma} V_\lambda$ for some sub-semigroup $\Gamma \leq \chi_+$. Further, restricting the action we get $k[Z]^U = \bigoplus_{\lambda \in \Gamma} V_\lambda^U$, a direct sum of one-dimensional subspaces corresponding to elements of Γ. Also, $k[Z]^U \cong k[\Gamma]$, where $k[\Gamma]$ is the semigroup ring of Γ.

3. Determinantal presentations and toric degenerations: making the bridge explicit

The abstract spherical-geometry discussion above (Vinberg–Kimelfeld multiplicity-freeness and Panyushev's deformation theorem) becomes computationally useful once one identifies *explicit U–covariants* and their relations. In essentially all representation-theoretic situations that occur in this manuscript, those covariants are given by *determinants*—minors of matrices encoding linear maps along paths in quivers, or Plücker-type minors on Grassmannians and flag varieties. This is precisely the input that makes toric degenerations accessible: straightening relations among determinants (Laplace and Cauchy–Binet identities) degenerate to binomial relations in a semigroup algebra.

The goal of this section is therefore twofold:

(i) to record, in a self-contained determinantal form, the standard relations that govern these covariants (Plücker/straightening identities), and
(ii) to explain why the corresponding associated graded rings are toric (semigroup) rings, matching the semigroup picture $k[Z]^U \cong k[\Gamma(Z)]$ in the spherical setting.

[7] D. Panyushev. *On Deformation Methods in Invariant Theory*. Ann. Inst. Fourier, Grenoble 47, 1 (1997), 985-1012.

We begin with the classical test case of Grassmannians and Schubert varieties, because it is the cleanest place where determinantal identities, standard monomial theory, and toric degenerations can all be written down explicitly. We then connect to the determinantal geometry of *circular complexes* used in the special-biserial moduli-space theorem of Carroll–Chindris–Kinser–Weyman [38] and to Schreiber's affine-Grassmannian viewpoint for surface orders [37].

3.1. Grassmannians: Plücker coordinates and determinantal relations. Fix a field K of characteristic 0 and an n–dimensional K–vector space V. For $1 \le k \le n$, the Grassmannian $GrGr(k, V)$ is a projective K–variety with a natural action of $G = \mathrm{GL}(V)$, and it is a basic example of a spherical G–variety.

Choose a basis of V and identify a point of $GrGr(k, V)$ with the row span of a full-rank $k \times n$ matrix X. For each k–subset $I = \{i_1 < \cdots < i_k\} \subset \{1, \ldots, n\}$, denote by

$$p_I(X) := \det(X_I)$$

the maximal minor of X in columns I. The Plücker embedding

$$GrGr(k, V) \hookrightarrow \mathbb{P}\Big(\bigwedge^k V\Big)$$

has homogeneous coordinates $\{p_I\}$, and the homogeneous coordinate ring of $GrGr(k, V)$ is the subring of $K[p_I]$ cut out by the Plücker relations.

Theorem 3.1 (Plücker relations as a determinantal identity). *Fix a $(k-1)$–subset $A \subset \{1, \ldots, n\}$ and a $(k+1)$–subset $B = \{b_1 < \cdots < b_{k+1}\} \subset \{1, \ldots, n\}$. Then the Plücker coordinates satisfy the quadratic identity*

$$\sum_{r=1}^{k+1} (-1)^{r-1}\, p_{A \cup \{b_r\}}\, p_{B \setminus \{b_r\}} \;=\; 0. \tag{3.1}$$

Equivalently, the 2×2 minors of the matrix of Plücker coordinates obtained by arranging $\{p_{A \cup \{b_r\}}\}$ and $\{p_{B \setminus \{b_r\}}\}$ in columns vanish.

Proof. Let $W \in GrGr(k, V)$ and choose vectors $w_1, \ldots, w_{k+1} \in W$. Since $\dim W = k$, we have $w_1 \wedge \cdots \wedge w_{k+1} = 0$ in $\bigwedge^{k+1} V$. Expand each w_j in the fixed basis of V and apply multilinearity of the wedge product. The coefficient of any basis wedge $e_{i_0} \wedge e_{i_1} \wedge \cdots \wedge e_{i_k}$ is a $(k+1) \times (k+1)$ determinant built from the coordinate matrix of the w_j's. Grouping terms by Laplace expansion along the column indexed by b_r produces exactly (3.1), with the signs coming from the alternating nature of the wedge. □

Remark 3.2 (Straightening law viewpoint). The quadratic relations (3.1) are the prototypical *straightening relations* for minors. They are the degree-2 manifestation of the general straightening law discussed in Section 2, and they imply that products of incomparable Plücker coordinates can be rewritten as K–linear combinations of *standard* products (chains in the dominance/poset order on k–subsets).

3.2. Schubert varieties: rank conditions and determinantal ideals. Fix a complete flag $0 \subset F_1 \subset \cdots \subset F_n = V$. Schubert subvarieties of $GrGr(k, V)$ are cut out by *rank conditions*

$$\dim(W \cap F_j) \ge a_j, \qquad j = 1, \ldots, n,$$

and in coordinates these conditions are expressed by vanishing of appropriate minors of the matrix X representing W. Thus Schubert varieties are determinantal varieties inside $GrGr(k, V)$ (and hence inside projective space via Plücker).

For the purposes of this manuscript the key point is structural:

> *the coordinate rings of Schubert varieties admit standard monomial theory, so their defining relations are governed by determinantal straightening.*

This is the mechanism that makes toric degenerations and multiplicity-free filtrations compatible with the spherical picture.

3.3. Why this produces toric degenerations: initial algebras of determinantal straightening laws. A toric degeneration is, at heart, a statement that a non-toric coordinate ring has a filtration whose associated graded ring is a semigroup (toric) ring. In the spherical setting, Panyushev's theorem gives a canonical filtration: the $\leq$–filtration by highest weights. In the determinantal setting, one often uses a monomial/term-order filtration compatible with straightening.

The two viewpoints are consistent because the generators (minors) are highest-weight vectors, and the straightening partial order is itself a shadow of the dominant weight order. Concretely, one obtains a *SAGBI* degeneration in which:

- the generators are minors (Plücker coordinates, generalized minors, or Schofield determinants),
- each straightening relation has a distinguished "leading" monomial (the nonstandard product),
- the associated graded algebra is generated by the same symbols subject only to binomial relations, hence is a semigroup ring.

Proposition 3.3 (Toric associated graded from a straightening law). *Let A be a finitely generated K–algebra generated by a finite partially ordered set $S = \{s_1, \ldots, s_N\}$. Assume A admits a straightening law in the sense of Section 2 such that for every incomparable pair $s, s' \in S$ the straightening relation has the form*

$$s\,s' \;=\; \sum_i c_i\, M_i,$$

where each M_i is a standard *monomial that is strictly smaller than ss' in a fixed term order. Then the associated graded algebra* $\mathrm{GrGr}(A)$ *for the induced filtration is a semigroup ring (hence the coordinate ring of an affine toric variety).*

Proof sketch. By hypothesis, the standard monomials form a K–basis and every nonstandard product reduces to a K–linear combination of smaller standard monomials. Passing to the associated graded kills all lower-order correction terms, so the straightening relations degenerate to *monomial/binomial* relations among the generators. The resulting algebra is thus the quotient of a polynomial ring by an ideal generated by binomials (and possibly monomials), i.e. a semigroup algebra. □

Remark 3.4 (Spherical interpretation). When $A = k[Z]^U$ for a spherical G–variety Z, the semigroup ring in Proposition 3.3 is precisely $k[\Gamma(Z)]$. In this sense, determinantal straightening is an *explicit* presentation of the abstract multiplicity-free semigroup phenomenon.

3.4. Affine Grassmannians, minors, and the surface-order viewpoint (after Schreiber). Schreiber emphasizes that loop-group/affine-Grassmannian charts are naturally coordinatized by minors that play the role of Plücker coordinates in infinite rank [37]. On the "big cell" of an affine Grassmannian (or of an affine flag variety) one may write elements as semi-infinite block matrices, and the relevant Plücker-type coordinates are again determinants of finite minors. These minors restrict to polynomial functions on the big cell, giving a determinantal coordinate algebra that is compatible with Schubert stratifications (and hence with toric degenerations arising from affine Schubert theory). This is exactly the bridge between the order-theoretic gluing picture and the representation-theoretic Schubert picture.

Remark 3.5 (Determinantal invariants and toric semigroup rings in the surface-algebra setting (Schreiber I)). In the dessin/surface-algebra setting, Schreiber repeatedly emphasizes that natural (rational) invariants are often *determinantal*—built from determinants of local path matrices or from minors encoding how local cyclic modules glue [36]. One motivation given there is that these determinantal

invariants frequently generate semigroup (toric) coordinate rings. From the point of view of this chapter, this is not a coincidence but an instance of the general mechanism:

$$\text{(determinants/minors)} \quad + \quad \text{(straightening)} \quad \Longrightarrow \quad \text{(semigroup / toric degeneration).}$$

This is exactly the form needed later when we interpret renormalization/coarse-graining as passing to associated graded (toric) models.

3.5. Circular complexes: determinantal rank conditions and an explicit degeneration argument. We now recall the determinantal geometry of *circular complexes* used in [38].

Fix an integer $\ell \geq 1$ and an ℓ–tuple of positive integers $n = (n_i)_{i\in\mathbb{Z}/\ell\mathbb{Z}}$. Consider the cyclic quiver with vertices $\mathbb{Z}/\ell\mathbb{Z}$ and arrows $a_i : i \to i+1$ (indices mod ℓ), together with relations

$$a_{i+1}a_i = 0 \qquad \text{for all } i \in \mathbb{Z}/\ell\mathbb{Z}.$$

A representation of this bound quiver is a tuple of matrices

$$A_i \in \mathrm{Mat}_{n_{i+1}\times n_i}(K) \quad \text{with} \quad A_{i+1}A_i = 0.$$

The corresponding representation variety is the *variety of circular complexes*

$$\mathrm{Comp}(n) := \Big\{(A_i)_i \in \prod_{i\in\mathbb{Z}/\ell\mathbb{Z}} \mathrm{Mat}_{n_{i+1}\times n_i}(K) \ : \ A_{i+1}A_i = 0 \ \forall i\Big\}.$$

Now fix a *rank sequence* $r = (r_i)_{i\in\mathbb{Z}/\ell\mathbb{Z}}$ satisfying the obvious inequalities $r_{i-1} + r_i \leq n_i$. Define the rank-bounded subvariety

$$\mathrm{Comp}(n, r) := \Big\{(A_i) \in \mathrm{Comp}(n) : \mathrm{rank}(A_i) \leq r_i \ \forall i\Big\}.$$

Each constraint $\mathrm{rank}(A_i) \leq r_i$ is determinantal: it is equivalent to vanishing of all $(r_i+1)\times(r_i+1)$ minors of A_i. Thus $\mathrm{Comp}(n, r)$ is cut out by a mix of quadratic equations (the composition relations) and determinantal equations (minors).

The key geometric fact (proved in [38], following Lusztig) is that the "expected" rank stratum is dense:

Lemma 3.6 (Rank-stratum closure equals the determinantal variety). *Let r be a rank sequence for n. Let*

$$\mathrm{Comp}^0(n, r) := \Big\{(A_i) \in \mathrm{Comp}(n) : \mathrm{rank}(A_i) = r_i \ \forall i\Big\}.$$

Then $\mathrm{Comp}(n, r)$ *is the Zariski closure of* $\mathrm{Comp}^0(n, r)$*, hence is irreducible.*

Proof idea (degeneration). The inclusion $\overline{\mathrm{Comp}^0(n, r)} \subseteq \mathrm{Comp}(n, r)$ follows from upper semicontinuity of rank. For the reverse inclusion, start from an arbitrary point $(A_i) \in \mathrm{Comp}(n, r)$ and write $r'_i := \mathrm{rank}(A_i) \leq r_i$. One constructs an explicit 1–parameter family of representations over $K[\lambda]$ that has generic fibre of rank sequence r and special fibre of rank sequence r' (and hence degenerates to the chosen point after acting by $\mathrm{GL}(n)$). Concretely, one adds, along each arrow a_i, a direct-summand representation supported only on the two endpoints and scaled by λ^{ε_i} with $\varepsilon_i = r_i - r'_i$. For $\lambda \neq 0$ this summand upgrades the rank to r_i, while at $\lambda = 0$ the summand vanishes. This produces a degeneration from a rank-r point to the rank-r' point, showing every point of $\mathrm{Comp}(n, r)$ lies in the closure of $\mathrm{Comp}^0(n, r)$. □

Proposition 3.7 (Normality via affine Schubert charts). *For any rank sequence r for n, the variety* $\mathrm{Comp}(n, r)$ *is normal.*

Proof sketch. Orbit closures in $\mathrm{Comp}(n)$ are orbit closures of nilpotent representations of cyclic quivers of type $\widetilde{A}$. Lusztig's local model theorem identifies these orbit closures with affine Schubert varieties in an appropriate (type A) affine flag variety. Affine Schubert varieties are normal (e.g. by the normality theorem of Faltings for algebraic loop groups). Therefore each $\mathrm{Comp}(n, r)$ is normal. See [38] for this reduction in the circular-complex setting, and the cited local-model inputs [34, 35]. □

Remark 3.8 (Why this is a determinantal proof in spirit). Both inputs—rank constraints and Schubert local models—are determinantal. Rank constraints are literally vanishing of minors. Affine Schubert varieties in type A can be presented by rank conditions on semi-infinite matrices (generalized determinantal equations), and their standard monomial theory is again governed by determinantal straightening. Thus the normality statement is not a black box: it is a manifestation of determinantal geometry at infinite rank.

Remark 3.9 (Back to spherical/toric degenerations). The determinantal presentation of $\mathrm{Comp}(n, r)$ means its coordinate ring is built from minors and their straightening relations. Whenever one chooses a compatible term order (or highest-weight filtration), the associated graded ring is a semigroup ring, hence $\mathrm{Comp}(n, r)$ admits toric degenerations. In the surface-order setting, these degenerations are the algebraic shadow of passing from a glued, curved geometry to a combinatorial skeleton, exactly as in Panyushev's horospherical contraction.

4. Determinantal invariants for gentle/surface algebras and their toric degenerations

The preceding section (§13) sketched the *geometric* slogan

$$\text{“spherical”} \implies \text{multiplicity free} \implies \text{toric degeneration},$$

and then explained how Zelevinsky-style wiring diagrams provide a *combinatorial* parametrization of totally positive pieces of groups and flag varieties. For the applications in later chapters (notably the determinantal Hilbert–Pólya closure argument), we need a second slogan that is less poetic and more computational:

> *The semi-invariants and many derived invariants of gentle/surface algebras are* ***determinants*** *of explicit maps, and under toric/horospherical degeneration these determinants become* ***monomials****.*

This section records the determinantal input with enough detail to be used as a black box later, while keeping the exposition compatible with both the *state-vector* and *density-operator* narratives used throughout the manuscript.

4.1. Schofield determinants and determinantal semi-invariants (quivers with relations). Let k be an algebraically closed field of characteristic 0. Let Q be a finite quiver, $I \subset kQ$ an admissible ideal of relations, and $A = kQ/I$ the bound quiver algebra. Fix a dimension vector $Grd = (d_i)_{i \in Q_0}$ and denote the representation variety by

$$\mathrm{GrRep}(A, Grd) \subseteq \prod_{a: i \to j \in Q_1} \mathrm{Mat}_{d_j \times d_i}(k),$$

cut out by the polynomial equations corresponding to the relations in I. The base-change group

$$G_{Grd} := \prod_{i \in Q_0} \mathrm{GL}_{d_i}(k)$$

acts on $\mathrm{GrRep}(A, Grd)$ by simultaneous change of bases at vertices. Write $\mathrm{SL}_{G\,rd} := \prod_i \mathrm{SL}_{d_i}(k)$.

Definition 4.1 (Semi-invariants). The *ring of semi-invariants* is

$$\mathcal{SI}(A, Grd) := k[\mathrm{GrRep}(A, Grd)]^{\mathrm{SL}_{G\,rd}}.$$

Equivalently, $\mathcal{SI}(A, Grd)$ is the direct sum of weight spaces for the G_{Grd}-action:

$$\mathcal{SI}(A, Grd) = \bigoplus_{\chi \in X^*(G_{Grd})} \mathcal{SI}(A, Grd)_\chi, \qquad g \cdot f = \chi(g)\, f \ \text{ for } f \in \mathcal{SI}(A, Grd)_\chi.$$

The fundamental point is that the *basic semi-invariants are determinantal*. One convenient formulation uses projective presentations.

Definition 4.2 (Determinantal semi-invariant from a projective presentation). Let $P_1 \xrightarrow{\phi} P_0 \to M \to 0$ be a finite projective presentation of a (finite-dimensional) A-module M. For $N \in \mathrm{GrRep}(A, Grd)$, applying $\mathrm{Hom}_A(-, N)$ yields a linear map

$$\mathrm{Hom}_A(P_0, N) \xrightarrow{\mathrm{Hom}(\phi, N)} \mathrm{Hom}_A(P_1, N).$$

When $\dim_k \mathrm{Hom}_A(P_0, N) = \dim_k \mathrm{Hom}_A(P_1, N)$ (a weight/dimension-match condition depending on M and Grd), define the *determinantal semi-invariant*

$$c^M(N) \;:=\; \det\big(\mathrm{Hom}_A(\phi, N)\big).$$

Remark 4.3 (Why this is the right determinant). Definition 4.2 recovers Schofield's semi-invariants in the acyclic case and their standard generalizations to quivers with relations. The key facts are:

(i) c^M is a semi-invariant of a specific weight determined by M;

(ii) varying M (or equivalently varying the presentation) produces enough determinants to generate $\mathcal{SI}(A, Grd)$;

(iii) the determinantal nature is robust under base change, which is exactly why these objects are appropriate for arithmetic applications (surface orders, local-to-global gluing).

We use these determinants as the algebraic "atoms" that will later be glued, filtered, and completed.

Theorem 4.4 (Generation by determinantal semi-invariants (informal statement)). *For a wide class of bound quiver algebras (including the gentle/special-biserial families relevant to surface algebras), the semi-invariant ring $\mathcal{SI}(A, Grd)$ is generated by determinantal semi-invariants c^M arising from suitable projective presentations of modules M.*

Proof sketch and references. In the acyclic case, Schofield constructed the semi-invariants c^M and showed that they generate the semi-invariant ring; Derksen–Weyman and Domokos–Zubkov recast this in a uniform determinantal framework. For quivers with relations, one replaces M by a presentation adapted to I and uses the same determinant-of-Hom-map mechanism. A detailed exposition is standard in invariant theory for quivers and is also the technical underpinning of the surface-algebra program in [36, 38]. □

4.2. Weighted Cartan determinants for (locally) gentle quivers: an explicit cycle product. A second determinantal invariant that is extremely well-adapted to surface/gentle combinatorics is the *Cartan determinant*. For finite-dimensional algebras it is classically a derived invariant (up to unimodular equivalence). For (possibly infinite-dimensional) *locally* gentle algebras, Bessenrodt–Holm compute a *weighted* Cartan determinant as a rational function whose factors are controlled by oriented cycles.

Definition 4.5 (Weighted locally gentle quiver and weighted Cartan matrix (informal)). A *weighted locally gentle quiver* is a locally gentle bound quiver (Q, I) together with a weight function $w : Q_1 \to k^\times$ (or with weights in a formal parameter ring), inducing a grading/weight on paths by multiplicativity. The *weighted Cartan matrix* $C_Q^w(x)$ is the matrix whose (i, j) entry is the weighted generating series of nonzero paths from j to i (the precise definition is given in [44]).

To state the determinant formula, denote by:

- $\mathrm{ZC}(Q)$ the set of minimal oriented cycles with *full relations* (every consecutive length-two subpath is in I),
- $\mathrm{IC}(Q)$ the set of minimal oriented cycles with *no relations* (no consecutive length-two subpath lies in I),
- for an oriented cycle $C = \alpha_1 \cdots \alpha_{\ell(C)}$, its weight $w(C) := \prod_{r=1}^{\ell(C)} w(\alpha_r)$ and length $\ell(C)$.

THEOREM 4.6 (Bessenrodt–Holm: determinant of the weighted Cartan matrix). *Let (Q, I, w) be a weighted locally gentle quiver and $C_Q^w(x)$ its weighted Cartan matrix. Then* $\det C_Q^w(x)$ *is a rational function determined entirely by the oriented cycle combinatorics:*

$$\det C_Q^w(x) = \frac{\prod_{C \in \mathrm{ZC}(Q)} \Big(1 - (-1)^{\ell(C)}\, w(C)\Big)}{\prod_{C \in \mathrm{IC}(Q)} \Big(1 - w(C)\Big)}. \tag{4.1}$$

PROOF SKETCH AND WHY WE CARE. The proof in [44] proceeds by a reduction algorithm that removes cycles while tracking unimodular transformations of $C_Q^w(x)$, together with a duality argument (Koszul duality in the unweighted case). For this manuscript the key output is the *shape* of (4.1): a determinant becomes an explicit product of simple factors indexed by oriented cycles.

In other words, the Cartan determinant is a controlled *cycle zeta function* of the quiver. This is exactly the kind of object one can later match to: (i) Euler products (primes and prime powers), and (ii) trace/log-determinant expansions $\log\det(I - T) = -\sum_{n\geq 1} \frac{1}{n} \operatorname{Tr}(T^n)$ where $\operatorname{Tr}(T^n)$ is a closed-cycle count. □

REMARK 4.7 (Surface-order interpretation). For surface algebras coming from dessins or embedded ribbon graphs, the relevant oriented cycles are precisely those encoded by the permutation data $(\sigma_0, \sigma_1, \sigma_\infty)$: black/white vertex cycles (in σ_0 and σ_1) and face cycles (in σ_∞). The "full relations" vs "no relations" dichotomy matches the surface-algebra distinction between cycles killed by the ideal and cycles that remain admissible in the completed order. Thus (4.1) is a determinantal certificate that the algebra "remembers" its surface cycle structure in a rigid, multiplicative way.

4.3. Regular components, circular complexes, and toric (semi-)invariant geometry. The determinantal facts above become geometric once combined with the special-biserial/gentle structure theory. Recall from [38] (reviewed earlier) that:

(i) irreducible components of representation varieties of special biserial algebras reduce to products of varieties of circular complexes,

(ii) these varieties are normal and have rational singularities,

(iii) and the resulting GIT moduli components are products of projective spaces.

A product of projective spaces is the simplest kind of spherical variety and admits many toric degenerations (indeed it is already toric). This is the geometric backbone behind the "semi-invariants are toric" statements used in the Artin L-function discussion.

4.4. Semi-invariant rings as semigroup rings: a toric theorem for surface algebras. We now record the toric/monomial conclusion in the form that is most useful later.

THEOREM 4.8 (Toricity of semi-invariants for surface/gentle families (after Schreiber and CCKW)). *Let A be a surface algebra (or a gentle/special biserial algebra arising from a clean or bipartite dessin), and fix a dimension vector Grd. Then:*

(1) the semi-invariant ring $\mathcal{SI}(A, Grd)$ is a finitely generated semigroup ring *(hence the coordinate ring of an affine toric variety);*

(2) the relevant representation varieties are normal, Cohen–Macaulay, and have rational singularities in the regular components;

(3) moduli spaces of θ-semistable regular modules have irreducible components isomorphic to products of projective spaces (in particular, many components are projective lines in the band-module regime).

PROOF SKETCH: DETERMINANTAL ⇒ TORIC VIA DEGENERATION. Combine three ingredients:

(i) **Determinantal generators.** By Theorem 4.4, $\mathcal{SI}(A, Grd)$ is generated by determinants c^M.

(ii) **Spherical/horospherical contraction.** The representation varieties (and their covariant rings) carry reductive group actions; the Vinberg–Kimelfeld/Panyushev deformation machinery yields a flat degeneration to a multiplicity-free (spherical) associated graded object (see §13).

(iii) **Initial-term monomiality in the gentle/special-biserial regime.** In the gentle/special-biserial case, the determinantal semi-invariants admit combinatorial interpretations in terms of nonintersecting path families (LGV) on the underlying surface/ribbon graph. Under the degeneration, each determinant has a distinguished leading term corresponding to a unique extremal path family, hence becomes a monomial. Therefore the associated graded semi-invariant ring is a semigroup ring; flatness transports finite generation and normality properties back to the original ring. Finally, the moduli-space conclusions follow from the normality results and the decomposition theorem for moduli spaces in [38].

□

4.5. Artin L-functions and surface orders: determinants, monomials, and cyclic subgroups. The surface-order technology in [36] is explicitly designed so that local matrix orders compute local characteristic polynomials. For Artin L-functions this is the natural language because the Euler factors are already determinants of Frobenius matrices.

We isolate (and slightly rephrase) the statements used later as an "assisting theorem".

THEOREM 4.9 (Artin-theoretic determinantal/toric package (after [36])). *Let $K/\mathbb{Q}$ be a finite extension (Galois or not) and let $\rho : G(K/\mathbb{Q}) \to \mathrm{GL}(V)$ be a finite-dimensional complex representation. Then:*

(1) the local Euler factors can be written as determinants

$$L_p(\rho, s) = \det\Big(I - \rho(\mathrm{Frob}_p)\, N(p)^{-s} \;\Big|\; V^{I_p}\Big)^{-1},$$

with the usual inertia correction at ramified primes;

(2) by embedding the base-change action diagonally into a larger $\mathrm{GL}(n)$ *(summing over local matrix sizes), one may compute these local determinants inside the hereditary orders appearing in the surface-order pullback construction;*

(3) the rings of polynomial semi-invariants for these surface-order representation varieties are semigroup rings (affine toric), and the associated semistable regular moduli components are products of projective spaces;

(4) consequently, Artin L-functions admit factorizations into monomials *corresponding to cyclic subgroup characters (integral, not merely rational, after choosing the appropriate surface-order framework).*

REMARK 4.10 (Why this matters for GRH-strength Hilbert–Pólya). Items (1)–(2) explain why determinants are the correct local arithmetic language. Items (3)–(4) explain why toric/monomial structures are not aesthetic decoration: they are what makes it plausible that one can build *positive* transfer operators and control limits (weak-$*$ and trace-class) across a twist family. This is the bridge to the determinantal Hurwitz closure argument in the final chapter.

4.6. Artin holomorphy via cyclic (Brauer) induction and toric semigroup geometry. Theorem 4.9 distilled the surface-order input from [36]. Because later chapters treat Artin twists and GRH-strength families, we now expand two points that were only implicit above:

(i) why *every* Artin L–function is a *determinant* and, via Brauer induction, a *monomial* in cyclic (hence Hecke/Dirichlet) L–functions; and

(ii) how holomorphy questions can be expressed as *semigroup-algebra* questions that are naturally controlled by toric geometry.

The resulting package is exactly what is used later when we treat Hilbert–Pólya approximants as determinants and then close the argument by Hurwitz.

4.6.1. *Brauer–Artin monomialization: from cyclic subgroups to monomials.* Let G be a finite group. Write $R(G)$ for the Grothendieck group of complex representations (virtual characters), and similarly $R(H)$ for subgroups $H \leq G$.

Theorem 4.11 (Brauer induction / Artin's theorem on induced cyclic characters). *Every virtual character $\chi \in R(G)$ is an* integer *linear combination of characters induced from* one-dimensional *characters of* cyclic *subgroups:*

$$\chi \;=\; \sum_{r=1}^{m} a_r \,\mathrm{Ind}_{H_r}^{G}(\psi_r), \qquad a_r \in \mathbb{Z}, \quad H_r \leq G \text{ cyclic}, \quad \psi_r \in R(H_r) \text{ one-dimensional}.$$

Remark 4.12 (Why we include this). This is the exact representation-theoretic statement behind the slogan in [36, §14] that "Artin L–functions become monomials attached to cyclic local orders." The surface-order formalism does *not* change Brauer induction; it changes the *geometry* in which one computes the corresponding determinants and invariants, and it provides an invariant-theoretic (toric) way to organize cancellation/holomorphy constraints.

Corollary 4.13 (Artin L–functions as monomials in cyclic (Hecke) L–functions). *Let $K/\mathbb{Q}$ be a finite extension and let $\rho : G(K/\mathbb{Q}) \to \mathrm{GL}(V)$ be a complex representation with character χ_ρ. Then there exist cyclic subgroups $H_r \leq G(K/\mathbb{Q})$, one-dimensional characters ψ_r of H_r, and integers a_r such that*

$$L(s,\rho) \;=\; \prod_{r=1}^{m} L\big(s, \mathrm{Ind}_{H_r}^{G}(\psi_r)\big)^{a_r} \;=\; \prod_{r=1}^{m} L(s,\psi_r)^{a_r}, \tag{4.2}$$

where $L(s,\psi_r)$ denotes the Artin L–function for the one-dimensional character ψ_r (equivalently a Hecke L–function for the corresponding abelian extension).

Proof sketch. Apply Theorem 4.11 to χ_ρ. Artin L–functions are multiplicative in virtual characters and compatible with induction: $L(s, \mathrm{Ind}_H^G \psi) = L(s,\psi)$ for the induced representation (after identifying Euler factors), and $L(s,\chi_1+\chi_2) = L(s,\chi_1)L(s,\chi_2)$, $L(s,n\chi) = L(s,\chi)^n$. This yields (4.2). □

Remark 4.14 (Meromorphy is easy; holomorphy is the subtle part). Equation (4.2) expresses any Artin L–function as a *monomial* in degree-one (abelian) L–functions, but with possibly negative exponents. Since degree-one L–functions are meromorphic with controlled poles, this immediately implies meromorphy of $L(s,\rho)$. The problem of showing holomorphy in the critical strip for nontrivial irreducible ρ is exactly the cancellation problem created by negative exponents (Artin's holomorphy conjecture).

4.6.2. *Gabriel–Riedtmann "group representations without groups": Brauer trees, special biserial algebras, and the surface-order philosophy.* A recurring methodological claim in this manuscript is that one can often replace explicit *groups* (Galois groups, monodromy groups, or local decomposition groups) by *quivers with relations* whose representation theory retains precisely the data needed to compute determinantal invariants. This philosophy is not new: a classical and influential prototype is the paper of Gabriel and Riedtmann on *group representations without groups* [62].

What "without groups" means. The slogan refers to the phenomenon that, in large regions of modular representation theory, the stable/derived representation category of a finite group algebra is governed by a *combinatorial quiver model* (Auslander–Reiten translation quivers, mesh categories, and explicit quivers with relations) rather than by the group itself. In particular, for blocks with *cyclic defect groups*, the basic

algebras are (Morita equivalent to) *Brauer tree algebras*: symmetric special-biserial algebras whose quivers and relations are determined by a decorated tree with a cyclic ordering of edges at each vertex. Gabriel–Riedtmann's analysis packages this as: a block is controlled by a translation quiver/mesh category that can be written down *intrinsically*, without naming the ambient group [62].

Why this aligns with surface orders. Surface/dessin algebras and surface orders are likewise *special-biserial/gentle* in broad families and hence sit in the same geometric landscape as Brauer tree algebras. The surface-order pullback construction in [36] replaces local arithmetic stabilizers (decomposition groups, inertia, Frobenius) by explicit *hereditary orders* inside matrix algebras over local rings. From the representation-theoretic perspective, this is again "without groups": the local group action is encoded by a quiver-with-relations (or order) whose determinantal invariants are stable under base change and can be computed in a purely algebraic/geometric manner.

Connection to cyclic subgroups and Brauer induction. Brauer induction (Theorem 4.11) reduces arbitrary virtual characters to integer combinations induced from *cyclic* subgroups. On the modular side, cyclic defect is exactly the condition under which blocks admit Brauer-tree models. Thus, the same "cyclicity" that makes monomialization of Artin L–functions possible is also what makes quiver models canonical in the representation category. This is one reason the surface-order framework is well matched to Artin data: it is engineered to remember cyclic local pieces functorially.

Connection to necklaces and trace invariants. Once a representation problem is expressed in quiver form, the correct polynomial invariants are generated by *cycle words*. Concretely, Le Bruyn–Procesi identify $\mathrm{GL}(\mathrm{Grd})$-invariants on $\mathrm{GrRep}(Q, \mathrm{Grd})$ with the trace algebra generated by necklace traces [40]; Craw–Yamagishi/Lusztig extend this to quivers with relations and frozen vertices (Section 7.6.1) [41]. On the arithmetic side, the Euler factors are determinants and hence polynomials in traces of powers by Newton identities (Lemma 7.13). Therefore the combined message is:

> *once arithmetic representation data is recoded as quiver/order data, the "local Euler determinants" live in the same cycle/necklace trace algebra as the geometric invariants controlling moduli.*

Remark 4.15 (Practical implication for holomorphy arguments). In the determinantal holomorphy program, the difficult analytic step is to control cancellations of poles created by negative exponents in the Brauer–Artin monomialization (Remark after Corollary 4.13). The geometric input provided by "without groups" (Gabriel–Riedtmann) and "cycles generate invariants" (Le Bruyn–Procesi/Lusztig) is that *all relevant denominators and potential pole loci can be expressed in determinantal/cycle coordinates on explicit moduli spaces*. This is the point at which one can plausibly bring toric degenerations and positivity (Sections 4.4 and 1.3) to bear on the cancellation problem.

4.6.3. *Carroll–Chindris:* SL *semi-invariants,* GL *rational invariants, and rational moduli geometry.* A recurring theme in this manuscript is that *determinants* are the natural interface between: (i) representation varieties (and their invariant theory), and (ii) Euler factors of arithmetic L–functions. The work of Carroll–Chindris on acyclic gentle algebras makes this link completely explicit at the level of *rational invariant functions*.

Setup: $\mathrm{GL}(\mathrm{Grd})$–action and its derived subgroup. Fix a bound quiver algebra $A = kQ/I$ over an algebraically closed field k of characteristic 0, and a dimension vector $\mathrm{Grd} \in \mathbb{N}^{Q_0}$. The base-change group

$$G := \mathrm{GL}(\mathrm{Grd}) \ := \prod_{i \in Q_0} \mathrm{GL}(\mathrm{Grd}(i))$$

acts on the representation variety $\mathrm{Grrep}(A, \mathrm{Grd})$ by change of bases. Its derived subgroup is

$$G' := \mathrm{SL}(\mathrm{Grd}) \ := \prod_{i \in Q_0} \mathrm{SL}(\mathrm{Grd}(i)).$$

Semi-invariants as SL(Grd)–invariants. The character lattice of G is naturally identified with $\mathbb{Z}^{Q_0}$: a weight $\theta = (\theta_i)_{i\in Q_0}$ defines the character

$$\chi_\theta(g) \;:=\; \prod_{i\in Q_0} \det(g_i)^{\theta_i} \qquad (g = (g_i)_i \in G).$$

A polynomial function $f \in k[\mathrm{Grrep}(A, \mathrm{Grd})]$ is a *semi-invariant of weight* θ if

$$g \cdot f \;=\; \chi_\theta(g)\, f \qquad \forall\, g \in G.$$

Write $\mathcal{SI}(A, \mathrm{Grd})_\theta$ for the weight space of such semi-invariants. Because $\chi_\theta|_{G'} \equiv 1$, every semi-invariant is G'–invariant and one has the canonical weight decomposition

$$\mathcal{SI}(A, \mathrm{Grd}) \;:=\; k[\mathrm{Grrep}(A, \mathrm{Grd})]^{G'} \;=\; \bigoplus_{\theta\in\mathbb{Z}^{Q_0}} \mathcal{SI}(A, \mathrm{Grd})_\theta.$$

For an irreducible component $C \subseteq \mathrm{Grrep}(A, \mathrm{Grd})$, write $\mathcal{SI}(C)_\theta$ for the restriction of $\mathcal{SI}(A, \mathrm{Grd})_\theta$ to C.

Rational invariants as ratios of semi-invariants. Let $k(C)$ be the function field of an irreducible component C. Whenever $\mathcal{SI}(C)_\theta \neq 0$, any ratio f/g with $f, g \in \mathcal{SI}(C)_\theta$ defines a *G–invariant rational function* on C, because the χ_θ–factors cancel:

$$g \cdot \frac{f}{g} \;=\; \frac{\chi_\theta(g) f}{\chi_\theta(g) g} \;=\; \frac{f}{g}.$$

Thus $k(C)^G$ is naturally identified with the degree-0 fraction field of the graded ring $\bigoplus_{n\geq 0} \mathcal{SI}(C)_{n\theta}$ when θ is chosen so that the stable locus is nonempty.

Lemma 4.16 (Function field of the moduli equals the field of rational invariants). *Let $C \subseteq \mathrm{Grrep}(A, \mathrm{Grd})$ be an irreducible component and let $\theta \in \mathbb{Z}^{Q_0}$ be a weight such that the θ–stable locus C^s_θ is nonempty. Then the moduli space*

$$M(C)^{ss}_\theta \;:=\; \mathrm{Proj}\Big(\bigoplus_{n\geq 0} \mathcal{SI}(C)_{n\theta}\Big)$$

contains an open subset $M(C)^s_\theta$ which is a geometric quotient of C^s_θ by PGL(Grd)*, and one has an identification of function fields*

$$k(C)^{\mathrm{GL(Grd)}} \;\cong\; k\big(M(C)^{ss}_\theta\big).$$

Proof (recorded in [42]). This is precisely the content of King-style GIT for quiver moduli, and is stated as Remark 3 in [42]: $M(C)^s_\theta$ is the rational quotient of C by GL(Grd), hence the corresponding function fields agree. □

Carroll–Chindris geometric traits for acyclic gentle algebras. For triangular (acyclic) gentle algebras $A = kQ/I$, Carroll–Chindris prove two structural results that are especially relevant for our later "determinant ⇒ holomorphy" logic:

(a) **GL–rational invariants are rational.** For every irreducible component $C \subseteq \mathrm{Grrep}(A, \mathrm{Grd})$, the invariant field $k(C)^{\mathrm{GL(Grd)}}$ is a purely transcendental extension of k, with transcendence degree determined by the *generic decomposition* of C into indecomposable regular components [42, Theorem 1(1)].

(b) **Regular moduli are products of projective spaces.** If C is an irreducible regular component and θ is chosen so that $C^{ss}_\theta \neq \emptyset$ and the θ–stable summands are regular, then $M(C)^{ss}_\theta$ is a product of projective spaces [42, Theorem 1(2)].

Determinantal coordinates. Even more concretely, Carroll–Chindris exhibit a transcendence basis for $k(C)^{\mathrm{GL}(\mathrm{Grd})}$ in terms of *ratios of generalized Schofield determinantal semi-invariants* [42, Theorem 2]. This is exactly the algebraic structure we want for the analytic package later:

$$\text{“GL–invariant rational function”} \quad = \quad \text{“ratio of determinants”}.$$

Remark 4.17 (Why this matters for holomorphy in the Hilbert–Pólya program). The relevance for holomorphy is twofold.

(i) **Determinants are holomorphic in analytic parameters.** Schofield semi-invariants are determinants of explicit linear maps built functorially from $\mathrm{Grrep}(A, \mathrm{Grd})$ (cf. Theorem 4.4). Whenever the underlying matrix entries depend holomorphically on a spectral parameter s (e.g. through weights like $u_p = p^{-s}$ or more general “clock” phases), the numerator and denominator determinants are holomorphic in s.

(ii) **Pole loci are geometric boundary divisors.** On a product of projective spaces, the possible poles/zeros of a ratio of homogeneous coordinates occur only along explicit boundary divisors. Under toric degeneration, these divisors become coordinate hyperplanes, so “no poles” becomes a statement about *nonnegativity of exponent vectors* in an affine semigroup. This is the geometric origin of the semigroup-algebra holomorphy criterion in Proposition 4.20.

Hilbert–Pólya / Hilbert–Polya bridge. The relevance of the Carroll–Chindris picture for the *Hilbert–Pólya (Hilbert–Polya)* program is that it provides, on the *representation-theoretic side*, a *canonical determinantal coordinate system*: the generic $\mathrm{GL}(\mathrm{Grd})$–quotient $C//\mathrm{GL}(\mathrm{Grd})$ is controlled by ratios of Schofield-type determinants. In the analytic part of the manuscript we package these ratios into *spectral determinants* of self-adjoint (or symmetrizable) transfer operators; the point is that the *same objects* now serve two roles:

(i) as algebraic coordinates on moduli (hence rational/toric control of poles and zeros as divisors), and

(ii) as Euler-factor building blocks of operator determinants (hence holomorphy and zero-location by operator theory).

This is the explicit place where invariant theory feeds the Hilbert–Pólya operator construction rather than appearing as a parallel narrative.

4.6.4. *Semigroup algebras of holomorphic L–functions and a toric holomorphy criterion.* Fix a point $s_0 \in \mathbb{C}$ (typically $s_0 \neq 0, 1$). Consider the multiplicative semigroup of Artin L–functions that are holomorphic at s_0.

Definition 4.18 (Holomorphy semigroup at s_0). Let $\mathcal{L}$ be the set of Artin L–functions for a fixed extension K/F (or a fixed global Galois group G). Define

$$H(s_0) \;:=\; \{\, L(s,\chi) \in \mathcal{L} \;:\; L(s,\chi) \text{ is holomorphic at } s = s_0 \,\},$$

with multiplication induced by multiplication of meromorphic functions.

Definition 4.19 (Semigroup algebra of holomorphy). Given a field $k \subset \mathbb{C}$, define the semigroup algebra

$$k[H(s_0)] \;:=\; \Big\{ \sum_{\ell} c_\ell\, h_\ell \;:\; c_\ell \in k,\; h_\ell \in H(s_0) \Big\},$$

with multiplication induced by $H(s_0)$.

The point is that $k[H(s_0)]$ is naturally an *affine semigroup ring* once one fixes a finite generating set of cyclic L–functions (coming from Brauer induction). Affine semigroup rings are precisely coordinate rings of affine toric varieties.

Proposition 4.20 (Toric holomorphy criterion (algebraic form)). *Assume that:*

(a) the cyclic/degree-one L–functions appearing in (4.2) *generate* $H(s_0)$ *as a semigroup, and*

(b) the semigroup algebra $k[H(s_0)]$ *is (graded) isomorphic to a polynomial ring* $k[x_1, \ldots, x_r]$.

Then every Artin L–function $L(s, \rho)$ *that is* meromorphic *at* s_0 *is in fact* holomorphic *at* s_0 *unless it contains the trivial character as a summand (the known pole case). In particular, Artin holomorphy at* s_0 *reduces to checking that* $k[H(s_0)]$ *is polynomial.*

Idea. If $k[H(s_0)] \cong k[x_1, \ldots, x_r]$, then the semigroup $H(s_0)$ is free on r generators and has unique factorization in the multiplicative sense. A monomial expression with integer exponents in the generators is holomorphic at s_0 if and only if all exponents are ≥ 0 (negative exponents would introduce poles because generators are holomorphic and nonvanishing at s_0). Therefore any cancellation mechanism that would allow a negative exponent while remaining holomorphic is forbidden by freeness/unique factorization. This pins down the only possible poles to the known trivial-character factors. □

Remark 4.21 (Where surface algebras enter). Theorem 14.3 of [36] asserts that the relevant (semi)invariant rings for surface-order representation varieties are affine toric (semigroup) rings and that regular moduli components are products of projective spaces (often $\mathbb{P}^1$ in the band-module regime). In the cleanest cases, these toric coordinate rings *are* polynomial rings, and Proposition 4.20 becomes a concrete holomorphy certificate. Even when the ring is not polynomial, toric normality/Cohen–Macaulayness gives strong control over factorization and valuation semigroups, which is the correct algebraic substrate for the pole-cancellation problem.

4.6.5. *How this feeds the Hilbert–Pólya/Hurwitz closure.* From the perspective of Chapter 25, the only analytic facts needed about $\Lambda(s, \varpi)$ are:

(i) holomorphy in the open strip $0 < \Re(s) < 1$, and

(ii) a convergent logarithmic derivative expansion (4.2) in $\Re(s) > 1$.

The semigroup/toric perspective is precisely what makes (i) plausible from the surface-order model: it turns holomorphy into a *finitary* statement about exponent vectors in a semigroup. Once holomorphy is granted, the Hurwitz closure theorem (Theorem 6.3) becomes the *final analytic step*: all remaining work is pushed into constructing self-adjoint determinantal approximants and proving their convergence (Theorem 7.7).

4.7. Back to spherical varieties: why toric degeneration is the correct organizing principle. The spherical/toric framework is not limited to quivers. A general theorem of Alexeev–Brion [45] asserts that any affine (resp. polarized projective) spherical variety admits a flat degeneration to an affine (resp. polarized projective) toric variety. In practice this is implemented by filtrations coming from highest-weight combinatorics (string polytopes, Newton–Okounkov bodies, etc.). We will not reprove those deep results here; for us they serve as an organizing principle:

> *once one has determinantal generators, one should search for a filtration/degeneration where those determinants become monomials.*

In the gentle/surface setting, the LGV interpretation of minors and the Bessenrodt–Holm cycle determinant formula give precisely the kind of explicit control that makes the degeneration *computable* rather than merely existential.

Part 5

Geometric Methods: Coverings and Hom-Controlled Functors

CHAPTER 14

Hom-controlled Functors and Covering Theory

This chapter upgrades the earlier, mostly combinatorial use of coverings (Chapter 2.5–2.6) into a representation-theoretic *control principle*: many hard questions about the module category of a (surface/-gentle) algebra Λ can be reduced to easier questions on a (typically infinite) covering $\widetilde{\Lambda}$, provided one works with functors that are *Hom-controlled* in the sense of Zwara.

1. Hom-controlled functors: the control axiom

Let $\mathcal{A}, \mathcal{B}$ be k-linear additive categories (for us $\mathcal{A} = \text{mod-}\widetilde{\Lambda}$ and $\mathcal{B} = \text{mod-}\Lambda$), and let $F : \mathcal{A} \to \mathcal{B}$ be an additive functor.

Definition 1.1 (Hom-controlled functor (Zwara-style)). We say that F is *Hom-controlled* if there exists a (typically finite) indexing set $\Omega = \Omega(X, Y)$ and a canonical decomposition

$$\mathrm{Hom}_{\mathcal{B}}(FX, FY) \;\cong\; \bigoplus_{\omega \in \Omega} \mathrm{Hom}_{\mathcal{A}}(X, \omega \cdot Y)$$

functorial in (X, Y), where $\omega \cdot Y$ denotes a (deck-group) action on objects in $\mathcal{A}$, and such that composition in $\mathcal{B}$ corresponds to the obvious convolution on the right-hand side.

Remark 1.2 (Why this is the right notion here). In Galois covering situations, Ω is (a set of representatives of) the covering group G and $\omega \cdot Y$ is the translate gY. The point is not just a vector-space isomorphism: *functoriality* and *composition-compatibility* mean that vanishing/nonvanishing of morphisms, dimensions of Hom, and irreducibility properties can be read off from the cover.

1.1. Zwara's Hom-order and degeneration heuristics. A robust way to organize orbit closures in representation varieties is via *Hom-dimension inequalities*. Zwara's key observation (in various forms, depending on finiteness hypotheses) is that degenerations force monotonicity of Hom-dimensions:

$$M \rightsquigarrow N \quad \Longrightarrow \quad \dim_k \mathrm{Hom}_{\Lambda}(X, M) \;\le\; \dim_k \mathrm{Hom}_{\Lambda}(X, N) \quad \text{for all } X,$$

and similarly for $\mathrm{Hom}(M, X)$. In the gentle/surface regime we use this *not* as an all-purpose classification theorem, but as a *control heuristic*:

- lift the problem to $\widetilde{\Lambda}$ (where indecomposables are strings/bands and Hom is combinatorial),
- compute Hom-dimensions upstairs,
- push the inequalities (and their sharpness) back downstairs using Hom-controlledness.

This is particularly effective when Λ decomposes face-wise into circular-complex factors (Chapter 21–22): the cover replaces cyclic constraints by line constraints.

2. (1) Cyclic quivers and circular-complex algebras

2.1. The covering picture. Let $Q = \widetilde{A}_n$ be the oriented n-cycle with radical-square-zero relations (so representations are *circular complexes*, Chapter 21). Its universal cover is the bi-infinite line quiver $\widetilde{Q} \simeq A_\infty$ with the lifted relations, and the deck group is $\mathbb{Z}$ acting by translation.

Write $\Lambda = kQ/I$ and $\widetilde{\Lambda} = k\widetilde{Q}/\widetilde{I}$. The push-down functor

$$F : \text{mod-}\widetilde{\Lambda} \longrightarrow \text{mod-}\Lambda$$

is induced by identifying vertices modulo n and summing the translated structure maps.

2.2. Hom-control for the push-down. In this setting, F is Hom-controlled with $\Omega \simeq \mathbb{Z}$ (or a finite window when supports are finite), and one has a canonical decomposition

$$\mathrm{Hom}_{\Lambda}(FX, FY) \cong \bigoplus_{t\in\mathbb{Z}} \mathrm{Hom}_{\widetilde{\Lambda}}(X, \tau^t Y),$$

where τ^t is the translation action on the cover (deck action). Consequences:

- **Hom computations reduce to string calculus upstairs.** For $\widetilde{\Lambda}$, indecomposables are strings (and, in periodic situations, bands), so Hom is computed by overlaps of words.
- **AR-components downstairs are orbit-quotients upstairs.** Components in the Auslander–Reiten quiver of Λ arise as $\mathbb{Z}$-orbit quotients of components for $\widetilde{\Lambda}$; this is the clean mechanism by which tubes appear in cyclic settings.
- **Degeneration control.** Zwara-type Hom-inequalities can be tested upstairs and then transported downstairs using the decomposition formula.

3. (2) Self-injective algebras and AR-translation via coverings

Many surface-adjacent self-injective algebras (notably symmetric special-biserial algebras such as Brauer-graph algebras, Chapter 34) admit presentations as *orbit algebras* of repetitive constructions or as quotients of gentle covers. In such cases, the stable module category $\underline{\text{mod}}$-Λ carries a triangulated structure and the AR-translation satisfies $\tau \simeq \Omega^2\nu$ (with ν the Nakayama functor; for symmetric algebras, $\nu \simeq \mathrm{id}$, hence $\tau \simeq \Omega^2$).

3.1. Hom-controlled lift of almost split sequences. Let $\widetilde{\Lambda}$ be a (locally gentle) cover of a self-injective Λ with deck group G. Under mild finiteness assumptions on supports, the push-down F is Hom-controlled and preserves irreducibility of morphisms up to G-orbits. In practice this means:

- almost split sequences in mod-Λ can be lifted to G-equivariant families of almost split sequences upstairs, and
- the AR-quiver of Λ is obtained from the AR-quiver of $\widetilde{\Lambda}$ by identifying vertices and arrows along G-orbits (a stable translation-quiver quotient).

3.2. Connection to Paquette et al. theorems and the surface/AR dictionary. The manuscript already flags a "Liu–Paquette–" theorem as the entry point for describing Auslander–Reiten quivers of gentle surface algebras (Chapter 9 in the roadmap). The Hom-controlled viewpoint supplies the *mechanism* behind such theorems in the two settings mentioned thus far:

(1) **Cyclic quivers / circular complexes:** the AR-components predicted by the surface combinatorics (face cycles, anti-cycles, and their lengths) arise as orbit-quotients of the universal cover, hence can be recovered from string/band combinatorics plus the deck action.

(2) **Self-injective surface-adjacent algebras:** the stable AR-quiver is governed by the repetitive (or covering) construction; Paquette-type surface/arc models for mod-Λ (and for the derived/stable categories) can be interpreted as giving a geometric fundamental domain for the covering action on the AR quiver, with τ identified with the surface "rotation"/shift on arcs.

Remark 3.1 (What to check in computations). For a concrete algebra in this manuscript (e.g. a double simple cycle order or a Brauer graph algebra), to *use* this chapter one typically: (i) writes an explicit covering quiver $\widetilde{Q}$ (often the universal cover), (ii) identifies the deck group action G, (iii) computes strings/bands and Hom-spaces upstairs, (iv) quotients by G to read off AR-components and mesh relations downstairs, and (v) uses Zwara's Hom-inequalities as a sanity check on proposed degenerations or closure relations in the representation varieties.

4. Hom-controlled push-down along Galois coverings (Zwara–Riedtmann)

4.1. Setup: coverings of bound quivers and the push-down functor. Let k be algebraically closed. Let $(\widetilde{Q}, \widetilde{I}) \to (Q, I)$ be a (connected) *Galois covering* of bound quivers with deck group G (in the sense of Riedtmann's covering theory for locally bounded categories). Write $\widetilde{\Lambda} := k\widetilde{Q}/\widetilde{I}$ and $\Lambda := kQ/I$. Assume $\widetilde{\Lambda}$ is *locally bounded* and *locally finite* so that the categories of finitely presented representations $\mathrm{Grrep}^+(\widetilde{\Lambda})$ and $\mathrm{Grrep}(\Lambda)$ are Krull–Schmidt and Hom-finite.

There is a canonical *push-down* (a.k.a. covering) functor

$$F_\lambda : \mathrm{Grrep}^+(\widetilde{\Lambda}) \longrightarrow \mathrm{Grrep}(\Lambda),$$

defined on objects by *orbit-summing along fibers*: for a vertex $x \in Q_0$, choose a lift $\tilde{x} \in \widetilde{Q}_0$ and set

$$(F_\lambda M)(x) \;:=\; \bigoplus_{g\in G} M(g\tilde{x}), \qquad (F_\lambda M)(a) \;:=\; \bigoplus_{g\in G} M(g\tilde{a}),$$

where $\tilde{a}$ is a chosen lift of a. One checks independence of choices by the G-equivariance of the covering.

4.2. Zwara's "Hom-control" identity for coverings. The key mechanism is that F_λ is exact and controls Homs by a *direct-sum decomposition* over the deck group.

Theorem 4.1 (Hom-controlled decomposition for a Galois push-down). *Let $F_\lambda : \mathrm{Grrep}^+(\widetilde{\Lambda}) \to \mathrm{Grrep}(\Lambda)$ be the push-down of a Galois covering with deck group G. For any $M, N \in \mathrm{Grrep}^+(\widetilde{\Lambda})$ there is a natural isomorphism*

$$\mathrm{Hom}_\Lambda(F_\lambda M,\ F_\lambda N) \;\cong\; \bigoplus_{g\in G} \mathrm{Hom}_{\widetilde{\Lambda}}(M,\ {}^gN),$$

where ${}^gN$ denotes the G-translate (pullback along the deck transformation g). In particular,

$$\dim_k \mathrm{Hom}_\Lambda(F_\lambda M, F_\lambda N) \;=\; \sum_{g\in G} \dim_k \mathrm{Hom}_{\widetilde{\Lambda}}(M, {}^gN),$$

so F_λ is Hom-controlled in the strong sense: the Hom-dimension is determined by finitely many translated Hom-dimensions on the cover.

Proof. Write $x \in Q_0$ and fix lifts $\tilde{x} \in \widetilde{Q}_0$. By definition $(F_\lambda M)(x) = \bigoplus_{g\in G} M(g\tilde{x})$ and similarly for N. A Λ-morphism $\varphi : F_\lambda M \to F_\lambda N$ is a collection of linear maps $\varphi_x : (F_\lambda M)(x) \to (F_\lambda N)(x)$ commuting with all arrow maps. Writing φ_x in block form with respect to the direct-sum decompositions along G, we can project to the $(1, g)$-block

$$\varphi_x^{(g)} :\ M(\tilde{x}) \longrightarrow N(g\tilde{x}).$$

Naturality with respect to arrows forces these blocks to form a morphism of $\widetilde{\Lambda}$-representations $M \to {}^gN$. Conversely, given a family $(f_g : M \to {}^gN)_{g\in G}$, define φ_x by putting the (h, hg)-block equal to $({}^hf_g)_x : M(h\tilde{x}) \to N(hg\tilde{x})$; the G-equivariance of the covering ensures this is well-defined and yields a Λ-morphism. These constructions are inverse to each other and are compatible with composition, giving the stated isomorphism. □

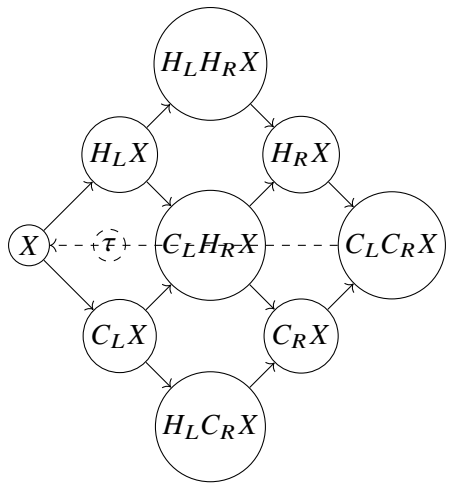

FIGURE 1. A schematic local AR mesh (diamond) in a string component. Solid arrows are irreducibles generated by hook/cohook moves; the dashed arrow indicates the Auslander–Reiten translation τ between opposite corners.

4.3. Geometric consequence: smoothness on module schemes. Let $\mathrm{Grrep}(\Lambda, Grd)$ denote the representation variety of dimension vector Grd (and similarly on the cover). Zwara's theory shows that Hom-control implies smoothness of the induced morphisms on module schemes and rank schemes.

COROLLARY 4.2 (Smoothness along covering images). *Fix dimension data so that F_λ maps* $\mathrm{Grrep}^+(\widetilde{\Lambda}, \tilde{Grd})$ *into* $\mathrm{Grrep}(\Lambda, Grd)$. *Then the induced morphism of schemes (on the corresponding strata)*

$$f_{Grd} : \mathrm{Grrep}^+(\widetilde{\Lambda}, \tilde{Grd}) \longrightarrow \mathrm{Grrep}(\Lambda, Grd)$$

is smooth. In particular, for any M on the cover, the étale-local singularity type of the orbit closure $\overline{O_{F_\lambda M}}$ in $\mathrm{Grrep}(\Lambda, Grd)$ *agrees with that of $\overline{O_M}$ in* $\mathrm{Grrep}(\widetilde{\Lambda}, \tilde{Grd})$ *up to a smooth factor.*

PROOF. The tangent space at a representation can be identified with derivations modulo inner derivations, and the obstruction space is governed by Ext^1. The decomposition of Theorem 4.1 shows that the linear maps controlling first-order deformations split into a direct sum over G, hence the differential of f_{Grd} is surjective (formally smooth). Finite-type hypotheses then imply smoothness. This is precisely the covering-specialized instance of Zwara's smoothness theorem for Hom-controlled functors. □

5. Auslander–Reiten components and TikZ illustrations

This section provides *explicit* translation-quiver pictures for the AR component types that occur in gentle/surface settings: (i) string components with local meshes (diamonds), (ii) homogeneous tubes for bands, and (iii) components containing projectives/injectives (preprojective/preinjective).

5.1. String components: a 9-vertex mesh (hook/cohook diamond). In a gentle algebra, irreducible maps between string modules are generated by the elementary operations of adding/removing a hook or a cohook at either end of the defining string. When both ends allow both moves, the local AR mesh consists of 9 indecomposables.

5.2. Band components: a homogeneous tube. Band modules form 1-parameter families; the corresponding stable component is a tube (a translation quiver of type $\mathbb{Z}A_\infty/\langle\tau^r\rangle$ for some rank r, with $r = 1$ in the homogeneous case).

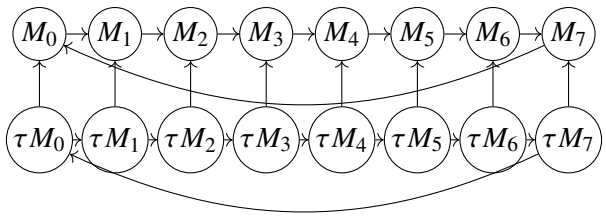

FIGURE 2. A schematic homogeneous tube component: τ acts by shifting one "row" down; horizontal arrows represent irreducible maps within the tube. The wrap-around indicates the cyclic identification (tube periodicity).

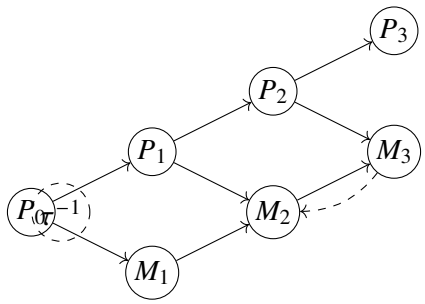

FIGURE 3. A schematic preprojective component (finite window): projectives P_i lie on a boundary; irreducible maps propagate "away" from projectives. The dashed arrow indicates the τ^{-1} direction schematically.

5.3. Preprojective/preinjective components. Components containing projectives/injectives in gentle/-surface algebras are typically of $\mathbb{Z}A_\infty$-type (or finite truncations), with projectives at one "end".

6. Self-injective algebras: stable AR translation and the Nakayama functor

Let Λ be a finite-dimensional self-injective algebra. Write ν for the Nakayama functor $\nu := D\operatorname{Hom}_\Lambda(-,\Lambda)$ and Ω for the syzygy functor on the stable category $\underline{\operatorname{mod}}\,\Lambda$.

THEOREM 6.1 (Stable AR translation for self-injective algebras). *In the stable category* $\underline{\operatorname{mod}}\,\Lambda$ *of a self-injective algebra, the Auslander–Reiten translation satisfies*

$$\tau \;\cong\; \Omega^2 \circ \nu.$$

If Λ *is moreover symmetric (so* $\nu \cong \mathrm{Id}$*), then* $\tau \cong \Omega^2$.

PROOF. For any finite-dimensional algebra, $\tau \cong D\operatorname{Tr}$ on nonprojective modules, where Tr is the transpose. For self-injective Λ, the stable category is Frobenius and Ω is an autoequivalence. One identifies $D\operatorname{Tr}$ with $\Omega^2\nu$ by comparing the standard projective presentation $P_1 \to P_0 \to M \to 0$ and its dual, using that injectives coincide with projectives and that ν accounts for the twist between left and right projectives in the duality. Concretely, the AR sequence ending in M is obtained from a minimal projective resolution of M by splicing, and the middle term identifies with $\Omega^{-1}\nu^{-1}\Omega M$, yielding $\tau \simeq \Omega^2\nu$. Symmetry implies $\nu \simeq \mathrm{Id}$, giving $\tau \simeq \Omega^2$. □

Part 6

Total Positivity, Wiring Diagrams, and Positivity of Energy

CHAPTER 15

Braid Group Action on Local Roots of Unity

1. Zelevinsky's Total Positivity and Wiring Diagrams

This section provides a *positivity technology* that we will reuse in several later places:

- in the QFT discussion (Wick rotation/transfer matrices), where positivity of Euclidean evolution underlies positivity of energy,
- in the renormalization-as-channel viewpoint, where we want certificates that coarse-grained transfer maps have controlled spectra, and
- in the Hilbert–Pólya/GRH program, where the analytic difficulty is to extract a *self-adjoint* generator from arithmetic/geometric input without hidden tuning.

The relevant mathematics is the theory of *total positivity* and its combinatorial parametrization by *wiring diagrams* (planar networks), developed in depth by Berenstein–Fomin–Zelevinsky and Fomin–Zelevinsky [22, 23], building on classical work of Gantmacher–Krein and Karlin [24, 25].

1.1. Totally nonnegative and totally positive matrices.

Definition 1.1 (Total nonnegativity and total positivity). A real matrix $A \in M_n(\mathbb{R})$ is *totally nonnegative* (TN) if every minor of A is ≥ 0. It is *totally positive* (all minors strictly positive) if every minor of A is > 0. We write $A \in GL_n^{\geq 0}$ (resp. $GL_n^{>0}$) if A is invertible and totally nonnegative (resp. totally positive).

Total positivity is much stronger than entrywise positivity. For example, a totally positive matrix is automatically invertible, and the inverse has a controlled sign pattern (checkerboard up to a positive diagonal scaling) [25, Ch. 1–2]. Two structural properties make total positivity / total nonnegativity useful as a *certificate* in physics-style constructions:

(i) **Spectral reality and simplicity.** Totally positive matrices are *oscillatory* in the Gantmacher–Krein sense, which forces all eigenvalues to be real, positive, and simple.

(ii) **Variation-diminishing (stability).** TN matrices are variation-diminishing: multiplying by a TN matrix cannot increase the number of sign changes of a vector, a discrete analogue of monotonicity/causality constraints.

We isolate the spectral statement we will use.

Theorem 1.2 (Gantmacher–Krein: totally positive $\Rightarrow$ real, simple, positive spectrum). *If $A \in GL_n^{>0}$ is totally positive, then A is diagonalizable over $\mathbb{R}$ with eigenvalues*

$$\lambda_1 > \lambda_2 > \cdots > \lambda_n > 0.$$

Moreover, the eigenvectors have strictly controlled sign-variation (the kth eigenvector has exactly $k-1$ sign changes).

Proof sketch / reference. A totally positive matrix is an *oscillatory matrix*: it is TN and some power has all minors strictly positive. The classical Gantmacher–Krein oscillation theorem then implies that the spectrum is real, positive, and simple, with the stated nodal/sign-variation properties of eigenvectors. A modern reference is [25, Thm. 2.5 and surrounding discussion]. □

1.2. Planar networks and the Lindström–Gessel–Viennot lemma. Total nonnegativity admits a concrete combinatorial realization via planar directed networks.

Definition 1.3 (Weighted planar network and its weight matrix). Fix n sources $s_1, \dots, s_n$ and n sinks $t_1, \dots, t_n$ arranged on the boundary of a planar disk in that cyclic order. Let $\mathcal{N}$ be a finite directed acyclic planar graph embedded in the disk, with all sources on one side and all sinks on the opposite side. Assign a nonnegative weight $w(e) \geq 0$ to each directed edge e. For a directed path $P = e_1 \cdots e_m$, define its weight $w(P) = \prod_{r=1}^{m} w(e_r)$. The *weight matrix* $A(\mathcal{N}) \in M_n(\mathbb{R})$ is

$$A(\mathcal{N})_{ij} := \sum_{P: s_i \rightsquigarrow t_j} w(P),$$

the sum of weights of all directed paths from s_i to t_j (finite because the network is acyclic).

Theorem 1.4 (Lindström–Gessel–Viennot (LGV)). *For any subsets $I, J \subset \{1, \dots, n\}$ with $|I| = |J| = k$, the minor* $\det A(\mathcal{N})_{I,J}$ *equals the sum of weights of all families of k pairwise vertex-disjoint directed paths connecting $\{s_i\}_{i \in I}$ to $\{t_j\}_{j \in J}$, with the appropriate sign determined by the induced matching. In particular, if all edge weights are nonnegative then every minor of $A(\mathcal{N})$ is nonnegative, hence $A(\mathcal{N})$ is TN.*

Proof sketch / reference. Expand the determinant by permutations. A sign-reversing involution cancels collections of paths with intersections, leaving only vertex-disjoint families. See [27, 26] for proofs. □

Corollary 1.5 (Wiring/network ⇒ total nonnegativity). *If $\mathcal{N}$ is a weighted planar network with nonnegative edge weights, then its weight matrix $A(\mathcal{N})$ is totally nonnegative. If in addition every relevant nonintersecting family exists and all edge weights are* strictly *positive, then $A(\mathcal{N})$ is totally positive.*

1.3. Positive Grassmannians and positive geometry: Postnikov and Arkani–Hamed et al. The wiring-diagram technology above can be phrased more invariantly in the language of *positive Grassmannians* and *boundary measurement maps*. This matters for two reasons:

(i) it supplies a conceptual explanation of why planar networks parametrize totally nonnegative objects (and why different network moves preserve positivity), and

(ii) it provides a bridge to the modern "positive geometry" viewpoint in mathematical physics, where positivity is not merely a technical lemma but a *structural axiom*.

Totally nonnegative Grassmannian. For $0 < k < n$, the *totally nonnegative Grassmannian* $GrGr_{\geq 0}(k, n)$ is the subset of the real Grassmannian $GrGr(k, n)$ consisting of k-planes whose Plücker coordinates can be chosen to be all nonnegative (and not all zero). Equivalently, $GrGr_{\geq 0}(k, n)$ is the closure of the locus where all Plücker coordinates are strictly positive.

Theorem 1.6 (Postnikov: boundary measurements parametrize cells of $GrGr_{\geq 0}(k, n)$). *Let $\mathcal{N}$ be a planar directed network embedded in a disk with n labeled boundary vertices, with positive edge weights. Postnikov's* boundary measurement map *assigns to $\mathcal{N}$ a point in $GrGr_{\geq 0}(k, n)$ (for an appropriate k determined by the source/sink data) whose Plücker coordinates are given by weighted sums of collections of nonintersecting directed paths in $\mathcal{N}$. Moreover, every cell of $GrGr_{\geq 0}(k, n)$ admits such a parametrization by a planar network, and network moves (square moves, reductions) correspond to changing coordinates within the same cell decomposition.*

Reference. This is the main structural output of Postnikov's work connecting planar networks, total positivity, and Grassmannian stratifications; see [49]. □

Remark 1.7 (Relation to LGV and total nonnegativity). The LGV lemma (Theorem 1.4) is the "matrix" shadow of the boundary measurement story: minors of a path matrix are sums of nonintersecting families, hence nonnegative. Postnikov upgrades this from matrices to *Plücker coordinates* and supplies a cell stratification and coordinate atlas on the positive locus. Thus, in this manuscript, whenever we realize a transfer matrix or a semi-invariant minor by a planar network, we are implicitly working in a chart on a positive Grassmannian cell.

Positive geometry in scattering amplitudes (Arkani–Hamed et al.). The positive Grassmannian reappears in mathematical physics through the identification of on-shell diagrams with cells of $GrGr_{\geq 0}(k, n)$ and the emergence of canonical differential forms with logarithmic singularities on boundaries. In particular, Arkani–Hamed and collaborators build a dictionary between:

$$\text{on-shell diagrams} \leftrightarrow \text{plabic graphs} \leftrightarrow \text{positive Grassmannian cells},$$

and propose "positive geometries" (including the *amplituhedron*) whose canonical forms encode amplitudes [50, 51, 52]. For our purposes, the relevance is methodological: it is an independent, physics-driven validation that *positivity constraints organize large determinantal computations* and that different combinatorial presentations (networks, plabic graphs, wiring diagrams) are equivalent positivity atlases.

Mirzakhani, moduli, and positivity of geometric measures. On the moduli-space side, Mirzakhani's work on Weil–Petersson volumes and the growth of simple closed geodesics produces *positive* volume polynomials/recursions and canonical ergodic measures on moduli spaces of hyperbolic surfaces [6]. In the present framework, this motivates two complementary uses of positivity:

(i) **Measure selection (ergodic input).** A canonical positive measure (e.g. Weil–Petersson) provides a natural stationary distribution for coarse-grained dynamics on cycle/lamination data, feeding directly into detailed-balance/self-adjointness arguments.

(ii) **Positivity of coordinates.** In decorated Teichmüller/cluster coordinate systems (lambda-length type coordinates), many naturally occurring functions on moduli are subtraction-free and hence positive on the positive locus; this is the moduli-space analogue of "positive network coordinates" on Grassmannians.

We will not attempt to reprove these deep geometric positivity statements here; we use them as a guide for choosing *canonical* positive structures rather than ad hoc sign conventions.

Remark 1.8 (Why "wiring diagrams" show up). A *wiring diagram* is a particularly rigid planar network: it is an arrangement of n monotone "wires" with crossings, encoding a reduced word in the symmetric group. The LGV lemma applies verbatim to wiring diagrams, and (because wiring diagrams are built by concatenating simple crossings) it meshes perfectly with factorization results in reductive groups.

1.4. Zelevinsky-style parametrization by wiring diagrams (factorization in $GL_n^{>0}$). One way to *construct* totally positive matrices is to factor them into elementary "Jacobi" matrices with positive parameters. Let E_{ij} denote the standard matrix unit. For $t > 0$ define the elementary upper- and lower-bidiagonal matrices

$$x_i(t) := I + tE_{i,i+1}, \qquad y_i(t) := I + tE_{i+1,i}, \qquad 1 \leq i \leq n-1,$$

and let $D = \mathrm{diag}(d_1, \ldots, d_n)$ with all $d_i > 0$. Products of these matrices are automatically totally nonnegative/totally positive, and Zelevinsky-type results show that (up to mild choices) *every* totally positive matrix arises this way.

THEOREM 1.9 (Berenstein–Fomin–Zelevinsky: wiring-diagram factorization). *Fix a reduced word* $Gri = (i_1, \dots, i_N)$ *for the long permutation* $w_0 \in S_n$. *Then the map*

$$(t_1, \dots, t_N; d_1, \dots, d_n) \longmapsto x_{i_1}(t_1) \cdots x_{i_N}(t_N)\, D\, y_{i_N}(t_N) \cdots y_{i_1}(t_1)$$

parametrizes an open dense subset of $GL_n^{>0}$, *and the reduced word* Gri *can be drawn as a wiring diagram whose crossings carry the parameters* t_r.

REFERENCE. This is one of the standard parametrizations of the totally positive part of a reductive group (here GL_n), expressed in terms of reduced words and generalized minors. See [22, 23]. □

REMARK 1.10 (Network interpretation). Each elementary factor $x_i(t)$ or $y_i(t)$ is the weight matrix of a tiny planar "crossing gadget" with a single tunable edge of weight t. Concatenating gadgets corresponds to matrix multiplication, hence the entire product in Theorem 1.9 is the weight matrix of an explicit wiring diagram network. Thus, by Corollary 1.5, total positivity of these products is a direct LGV consequence.

1.5. Total positivity as a positive-energy / self-adjointness certificate (Wick-rotated transfer matrices). In Euclidean (Wick-rotated) lattice QFT, one often works with a *transfer matrix* T rather than a unitary. The formal relation is $T = \exp(-aH)$ for lattice spacing $a > 0$. To conclude that H is self-adjoint and bounded below, one typically imposes Osterwalder–Schrader reflection positivity. Total positivity gives a more combinatorial (and, in discrete settings, sometimes easier to verify) sufficient condition.

THEOREM 1.11 (Symmetric totally positive transfer matrix ⇒ self-adjoint Hamiltonian with positive energy). *Let* $T \in M_n(\mathbb{R})$ *be* symmetric *and totally positive. Then:*

(a) T *has real, positive, simple eigenvalues* $\lambda_1 > \cdots > \lambda_n > 0$;

(b) for any $a > 0$, *the matrix*

$$H := -\frac{1}{a} \log T$$

is real symmetric (hence self-adjoint) with eigenvalues $E_k = -(1/a) \log \lambda_k \in \mathbb{R}$;

(c) after rescaling T *by its top eigenvalue (equivalently shifting* H *by a scalar), one may assume* $\lambda_1 = 1$, *in which case* $E_k \geq 0$ *for all* k *(positivity of energy).*

PROOF. (a) By Theorem 1.2, T has real, positive, simple eigenvalues. (b) Because T is symmetric, there exists an orthogonal matrix U with $T = U \operatorname{diag}(\lambda_1, \dots, \lambda_n)\, U^\top$. Define $\log T := U \operatorname{diag}(\log \lambda_1, \dots, \log \lambda_n)\, U^\top$; this is real symmetric. Then $H = -(1/a) \log T$ is real symmetric with eigenvalues E_k as stated. (c) Replace T by $\widetilde{T} := \lambda_1^{-1} T$. Then $\widetilde{T} = \exp(-a\widetilde{H})$ where $\widetilde{H} = H - (1/a) \log \lambda_1\, I$ is a scalar shift of H. Now $0 < \widetilde{\lambda}_k \leq 1$, hence $-\log \widetilde{\lambda}_k \geq 0$ and $\widetilde{H} \geq 0$. □

Worked example: a 2×2 totally positive transfer matrix. To make the theorem concrete, consider the simplest case: a symmetric 2×2 totally positive matrix

$$T = \begin{pmatrix} a & b \\ b & c \end{pmatrix}, \quad a, b, c > 0, \quad \det(T) = ac - b^2 > 0.$$

For total positivity, we need all minors positive: $a > 0$, $c > 0$, $\det(T) > 0$, which hold by assumption.

The eigenvalues are

$$\lambda_\pm = \frac{(a+c) \pm \sqrt{(a+c)^2 - 4(ac - b^2)}}{2} = \frac{(a+c) \pm \sqrt{(a-c)^2 + 4b^2}}{2}.$$

Both are real and positive (since $a, c, b > 0$), and $\lambda_1 > \lambda_2 > 0$ by the spectral ordering.

Now define $H = -\frac{1}{a}\log T$ (using Euclidean time step $a > 0$). Diagonalizing $T = U\mathrm{diag}(\lambda_1, \lambda_2)U^\top$ with an orthogonal U, we get

$$H = U\,\mathrm{diag}\left(-\frac{1}{a}\log\lambda_1, -\frac{1}{a}\log\lambda_2\right)U^\top.$$

This is manifestly real symmetric. Its eigenvalues are

$$E_1 = -\frac{1}{a}\log\lambda_1, \quad E_2 = -\frac{1}{a}\log\lambda_2.$$

If we rescale $T \to \widetilde{T} := \lambda_1^{-1}T$ so that $\widetilde{\lambda}_1 = 1$, then $\widetilde{E}_1 = 0$ and $\widetilde{E}_2 = -\frac{1}{a}\log(\lambda_2/\lambda_1) \geq 0$ (since $0 < \lambda_2 \leq \lambda_1$). Thus the shifted Hamiltonian has nonnegative spectrum—positive energy, as desired.

This example shows explicitly how total positivity of T (enforced via planar-network construction) leads to the required self-adjointness and spectral positivity without any appeal to Osterwalder–Schrader positivity or other limiting procedures.

1.6. Density-operator phrasing: totally positive transfer matrices as states and modular Hamiltonians. If T is symmetric and positive definite, then after normalization it is literally a density operator. Define

$$\rho := \frac{T}{\mathrm{Tr}(T)}.$$

Then $\rho \geq 0$, $\rho = \rho^\top$ and $\mathrm{Tr}(\rho) = 1$, so ρ is a finite-dimensional (real) density matrix. Its modular Hamiltonian is

$$K := -\log\rho = -\log T + \log\mathrm{Tr}(T)\,I.$$

Thus Theorem 1.11 can be reread as:

> *if a one-step Euclidean evolution operator is symmetric totally positive, then its normalized version is a bona fide density operator whose modular Hamiltonian is self-adjoint and nonnegative (after a scalar shift).*

Remark 1.12 (How this is used later). In the Hilbert–Pólya/GRH chapter we extract candidate generators from *channels* (CPTP maps) rather than from a single matrix. A common finite-dimensional reduction is to look at the channel's action on a commutative subalgebra (a coarse-grained classical shadow) or to restrict to a basis in which the channel becomes reversible. In such reductions, wiring-diagram/total-positivity conditions give a concrete, checkable route to self-adjoint modular generators.

Capstone: The architecture of total positivity in the Hilbert–Pólya program. We now summarize the complete picture that this chapter has built.

(i) **Combinatorial layer (Zelevinsky).** Wiring diagrams and planar networks provide a concrete, parameter-counting realization of totally positive matrices. By the Berenstein–Fomin–Zelevinsky factorization theorem, every totally positive $n \times n$ matrix factors as a product of elementary bidiagonal matrices with nonnegative parameters, and this factorization structure is encoded in a wiring diagram.

(ii) **Algebraic layer (Postnikov; positive Grassmannians).** The positive Grassmannian and its boundary measurement maps supply an invariant geometric language for positivity: wiring diagrams are coordinate charts on cells of $GrGr_{\geq 0}(k, n)$, and different network moves correspond to different coordinate patches on the same cell. This ties positivity to the underlying moduli geometry.

(iii) **Spectral layer (Gantmacher–Krein).** Totally positive matrices have *real, positive, and simple eigenvalues*. This is the crucial certificate: in any transfer-matrix or channel-based construction, total positivity automatically ensures the spectrum is real and bounded.

(iv) **Self-adjointness and energy (Wick rotation).** When a symmetric totally positive transfer matrix T is Wick-rotated via $H = -\frac{1}{a}\log T$, the resulting Hamiltonian is self-adjoint and, after a scalar shift,

has nonnegative eigenvalues (positive energy). This is exactly what the Hilbert–Pólya construction requires: a self-adjoint generator whose spectrum is real and controlled.

The synthesis is this:

> *A clock/shift operator built by gluing totally positive transfer matrices (via wiring-diagram concatenation) automatically yields a self-adjoint Hamiltonian with real spectrum and positive energy. The wiring diagram is the certificate of positivity; the Gantmacher–Krein theorem is the certificate of reality; the logarithm is the bridge to self-adjointness. This mechanism is the core of the Hilbert–Pólya proposal for GRH developed in the final chapters: we will construct candidate generators of time evolution from surface orders and arithmetic data, demand that they are (or factor through) totally positive transfer matrices, and thereby obtain self-adjoint operators whose spectrum encodes the Riemann zeros.*

This is the "icing in the middle of the cake"—a complete, self-contained layer that makes rigorous and checkable the claim that discrete/combinatorial/arithmetic input can yield a self-adjoint spectral problem with controlled reality and positivity properties.

CHAPTER 16

Wick Rotation and the Positivity of Energy in QFT

Bridge from total positivity

The total positivity machinery developed in the preceding chapter provides the *algebraic certificate* that certain transfer matrices have controlled spectra and self-adjoint logarithms. We now translate that machinery into the *physical language* of Wick rotation and positive energy—the form needed for the Hilbert–Pólya operator construction. The key insight is simple: a symmetric totally positive transfer matrix T, when analytically continued to imaginary Euclidean time via $H := i \log T$ (or equivalently $H = -\frac{1}{a} \log T$), automatically yields a self-adjoint Hamiltonian whose spectrum is real and, after normalization, nonnegative. This chapter makes the connection explicit and develops the quantum-field-theoretic context in which these transfer matrices arise naturally.

The basic analytic tension in QFT (and in any proposal that tries to build QFT-like dynamics from discrete/combinatorial input) is:

> *Lorentzian time evolution wants a self-adjoint Hamiltonian H (so that $U(t) = e^{-itH}$ is unitary), while Euclidean constructions and coarse-grained dynamics naturally produce* positive *transfer operators T (or channels) instead.*

A standard bridge between the two is **Wick rotation**:

$$t \mapsto -i\tau, \qquad U(t) = e^{-itH} \rightsquigarrow e^{-\tau H}.$$

On a lattice, τ is discretized and one works with a one-step transfer matrix T that formally satisfies $T = e^{-aH}$ for time step $a > 0$. The question is then: *when is $H := -(1/a) \log T$ actually self-adjoint and bounded below?*

1. Euclidean transfer matrices and positivity

In finite volume, a Euclidean path integral with real action S_E produces weights $e^{-S_E} \geq 0$ and hence a transfer matrix with nonnegative matrix elements in a preferred basis. In infinite volume, the right condition is *reflection positivity* (Osterwalder–Schrader positivity), which guarantees reconstruction of a Hilbert space and a self-adjoint Hamiltonian with spectrum bounded below.

For the purposes of this manuscript (which is explicitly constructive and often finite-dimensional at intermediate stages), it is useful to keep a clean, checkable sufficient condition:

> *If T is symmetric positive definite, then $H = -\frac{1}{a} \log T$ is self-adjoint, and energy positivity reduces to a normalization of the top eigenvalue.*

2. A wiring-diagram sufficient condition

Total positivity upgrades "T has nonnegative entries" to "every minor of T is positive", and this stronger property has two practical consequences: (i) it is stable under local concatenations, and (ii) it forces the spectrum to be real, positive, and simple.

The preceding chapter's total-positivity results immediately yield a Wick-rotation positivity statement.

Corollary 2.1 (Reflection-symmetric wiring diagram $\Rightarrow$ positive-energy Hamiltonian). *Let $\mathcal{N}$ be a positive-weight wiring-diagram network whose weight matrix $T = A(\mathcal{N})$ is* symmetric *(e.g. the network is invariant under planar reflection exchanging sources and sinks, which is a discrete detailed-balance condition). Assume $\mathcal{N}$ is such that T is totally positive (Corollary 1.5). Then $H := -(1/a)\log T$ is self-adjoint and (after a scalar shift/normalization) satisfies $H \geq 0$.*

Proof. By Corollary 1.5, T is totally positive. By hypothesis T is symmetric, so Theorem 1.11 applies. □

3. Density-operator viewpoint: Euclidean evolution as a Gibbs state

Given a positive definite transfer matrix T, one may form a finite-volume Gibbs state at inverse temperature β by

$$\rho_\beta := \frac{T^\beta}{\mathrm{Tr}(T^\beta)} = \frac{e^{-\beta a H}}{\mathrm{Tr}(e^{-\beta a H})}.$$

The modular Hamiltonian of ρ_β is

$$K_\beta := -\log \rho_\beta = \beta a H + \log Z(\beta)\, I, \qquad Z(\beta) = \mathrm{Tr}(e^{-\beta a H}).$$

Thus, in Euclidean settings the modular Hamiltonian is essentially the physical Hamiltonian (up to an affine transformation), and the "positivity of energy" is precisely the statement $K_\beta \geq 0$ after subtracting its scalar part. Total positivity provides one constructive route to guarantee that this modular generator is self-adjoint, with good spectral control, *before* taking any thermodynamic limit.

Part 7

Time, Holonomy, Hyperbolic Geometry, and Emergent Dynamics

CHAPTER 17

Time as a Shift Operator: finite and infinite qudits

The practical study of physical clocks—whether digital, mechanical, or quantum—reveals that temporal evolution is fundamentally encoded in shift dynamics: a clock's state advances from one value to the next via an operator that increments or cycles the internal register. This chapter formalizes this intuition by studying how shift operators generate the simplest non-trivial models of time, from finite-dimensional cyclic qudits to infinite-dimensional systems. Understanding the spectral and holonomic properties of these shifts forms the foundation for later chapters, where cyclic time emerges as torsion in the holonomy of glued local orders.

1. Finite-dimensional clocks: the cyclic shift and its spectrum

Fix a local Hilbert space $\mathcal{H} \cong \mathbb{C}^d$ with computational basis $\{|j\rangle\}_{j\in\mathbb{Z}/d\mathbb{Z}}$. Define the *shift* ("successor") operator

$$X_d|j\rangle = |j+1\rangle,$$

and the *phase* operator

$$Z_d|j\rangle = \omega^j|j\rangle, \qquad \omega = e^{2\pi i/d}.$$

Then $X_d^d = Z_d^d = I$ and the Weyl commutation relation holds:

$$Z_d X_d = \omega\, X_d Z_d.$$

The discrete Fourier transform F_d diagonalizes X_d:

$$F_d\, X_d\, F_d^{-1} = Z_d, \qquad (F_d)_{jk} = d^{-1/2}\,\omega^{jk}.$$

Thus the eigenvalues of X_d are $\{\omega^k\}_{k=0}^{d-1}$, and the "clock phases" advance uniformly.

2. Irrational rotation algebras and the noncommutative torus: from finite qudits to infinite clocks

The finite qudit Weyl relation

$$Z_d X_d = \omega\, X_d Z_d, \qquad \omega = e^{2\pi i/d},$$

is the "root of unity" case of a much more rigid operator-algebraic object: the *irrational rotation algebra* (also called the *noncommutative* 2*–torus*).

Definition 2.1 (Irrational rotation algebra / noncommutative torus). Fix $\theta \in \mathbb{R}$. The *rotation algebra* A_θ is the universal unital C^*–algebra generated by two unitaries U, V such that

$$VU = e^{2\pi i\theta}\, UV. \tag{2.1}$$

Remark 2.2 (Rational versus irrational phases). If $\theta = p/q \in \mathbb{Q}$ (in lowest terms), then (2.1) is the projective commutation relation of a finite q–level clock: one may take $U = X_q$ and $V = Z_q^p$ so that $VU = e^{2\pi i p/q}UV$. If $\theta \notin \mathbb{Q}$, then A_θ has *no* nontrivial finite-dimensional representations (Proposition 2.3), and one is forced into the infinite-clock regime.

Proposition 2.3 (Finite-dimensional representations force θ to be rational). *Suppose there exist unitaries* $U, V \in M_n(\mathbb{C})$ *satisfying* (2.1). *Then* $e^{2\pi i n\theta} = 1$, *hence* $\theta \in \frac{1}{n}\mathbb{Z} \subset \mathbb{Q}$.

Proof. Taking determinants on both sides of $VU = e^{2\pi i\theta}UV$ gives

$$\det(V)\det(U) = e^{2\pi in\theta}\det(U)\det(V).$$

Since $\det(U), \det(V) \neq 0$, cancel to obtain $e^{2\pi in\theta} = 1$. □

2.1. Crossed-product realization and dynamical meaning. A key structural fact is that A_θ is a crossed product by an irrational circle rotation.

Let $\mathbb{T} = S^1$ and let $\alpha_\theta : \mathbb{T} \to \mathbb{T}$ be the rotation $\alpha_\theta(z) = e^{2\pi i\theta}z$. Let α denote the induced automorphism of $C(\mathbb{T})$,

$$(\alpha(f))(z) := f(\alpha_\theta^{-1}z) = f(e^{-2\pi i\theta}z).$$

Then the crossed product $C(\mathbb{T}) \rtimes_\alpha \mathbb{Z}$ is the universal C^*–algebra generated by

- a copy of $C(\mathbb{T})$, and
- a unitary U implementing the $\mathbb{Z}$–action: $UfU^* = \alpha(f)$,

and is canonically isomorphic to A_θ by sending V to the coordinate function $V(z) = z$ and U to the implementing unitary. This is the standard "dynamics ⇒ noncommutative observable algebra" mechanism [30, 31].

2.2. Ergodic theory input: unique ergodicity and the canonical trace. For $\theta \notin \mathbb{Q}$, the rotation α_θ on the circle is *minimal* and *uniquely ergodic*: Lebesgue measure m is the unique α_θ–invariant Borel probability measure, and Birkhoff averages converge uniformly

$$\frac{1}{N}\sum_{k=0}^{N-1} f(\alpha_\theta^k z) \xrightarrow[N\to\infty]{} \int_{\mathbb{T}} f\,dm \quad \text{for all continuous } f \text{ and all } z \in \mathbb{T}$$

(see e.g. [33]).

This uniquely ergodic fact has a concrete operator-algebraic consequence:

Proposition 2.4 (Canonical trace on A_θ). *If $\theta \notin \mathbb{Q}$, then A_θ admits a unique tracial state τ characterized on Fourier monomials by*

$$\tau(U^mV^n) = \begin{cases} 1, & (m,n) = (0,0), \\ 0, & \textit{otherwise.} \end{cases}$$

Equivalently, in the crossed-product picture $A_\theta \cong C(\mathbb{T}) \rtimes_\alpha \mathbb{Z}$,

$$\tau\Big(\sum_k f_k U^k\Big) = \int_{\mathbb{T}} f_0\,dm.$$

Remark 2.5 (Why ergodicity is the right "physics" hypothesis). The heuristic "long-time averages equal equilibrium expectations" is *exactly* Birkhoff's theorem in the uniquely ergodic case. In our setting, τ is the canonical "equilibrium" state induced by the orbit geometry. When we use traces in later Hilbert–Pólya/explicit-formula discussions, this is the clean place where one justifies passing from orbit sums (time averages) to traces (state expectations).

2.3. Continued fractions, renormalization, and finite-clock approximants. A practical reason the rotation algebra belongs in a computational manuscript is that irrational parameters are naturally approximated by rational ones, and the corresponding algebras are realized by finite clocks.

Write the (infinite) continued fraction expansion

$$\theta = [a_0; a_1, a_2, a_3, \dots],$$

and let p_n/q_n be the convergents. Classical Diophantine approximation gives the uniform estimate

$$\left|\theta - \frac{p_n}{q_n}\right| < \frac{1}{q_n^2}.$$

Each rational approximant $\theta_n = p_n/q_n$ yields a finite-dimensional "magnetic translation" model:

$$A_{\theta_n} \text{ admits a faithful } q_n\text{–dimensional projective representation generated by } (X_{q_n}, Z_{q_n}^{p_n}).$$

Thus, *finite qudit clocks* are exactly the natural rational approximations to an irrational-clock observable algebra.

Remark 2.6 (Renormalization viewpoint and an ergodic map on parameters). The continued-fraction shift $\theta \mapsto [a_1; a_2, \dots]$ is the Gauss map $G(\theta) = \{1/\theta\}$ on $(0, 1)$, which is a paradigmatic ergodic dynamical system [33]. Interpreting "coarse-graining" as passing from θ to a better rational approximant p_n/q_n is therefore literally a renormalization flow on the space of rotation numbers. In the operator-algebraic classification of A_θ, this continued-fraction structure controls inductive-limit approximations by matrix algebras (the Elliott–Evans picture [32]), which is precisely what one wants for numerical and hardware-friendly truncations.

In short: irrational clocks can be simulated at scale by a multiscale ladder of finite qudits dictated by the continued fraction of θ, and ergodic theory governs the typical complexity of that ladder (digit statistics, mixing of the Gauss map), which in turn controls what a learned renormalization scheme must discover.

2.4. Density operators and modular Hamiltonians for rotation-algebra observables. A C^*–algebraic *state* is a positive linear functional $\omega : A_\theta \to \mathbb{C}$ with $\omega(1) = 1$. Once a concrete representation $\pi : A_\theta \to \mathcal{B}(\mathcal{H})$ is chosen, *normal* states are implemented by density operators:

$$\omega(a) = \mathrm{Tr}(\rho\, \pi(a)), \qquad \rho \geq 0,\ \mathrm{Tr}(\rho) = 1.$$

In particular, the tracial state τ of Proposition 2.4 is the infinite-temperature limit in which the modular Hamiltonian is trivial (the modular flow is identity). Nontrivial modular Hamiltonians appear once one specifies a one-parameter dynamics $\{\sigma_t\}$ on A_θ (e.g. a one-parameter subgroup of the natural $\mathbb{T}^2$–action) and chooses a corresponding KMS state; then Tomita–Takesaki theory produces a modular generator compatible with the ergodic geometry.

2.5. Why this belongs in the "clock" chapter. Two points link A_θ directly to our holonomy-as-time story:

(1) **Finite clocks are rational noncommutative tori.** The pair (X_d, Z_d) generates a finite-dimensional projective representation of $\mathbb{Z}^2$ with a $U(1)$ 2–cocycle (the phase ω). The irrational rotation algebra is the C^*–completion when the cocycle phase is irrational and cannot close in finite dimension.

(2) **Quasi-periodic time is ergodic time.** If "time" is generated by a shift U whose action on a commutative subalgebra is an irrational rotation, then repeated ticking explores the entire phase circle uniformly. This makes the trace state computable by orbit averaging and provides the ergodic underpinning for replacing long products of local clock moves by trace-class expressions later.

2.6. Procyclic root towers and "infinite-period" cyclic qudits. The rotation algebra A_θ is the analytic completion of a *single* irrational rotation on a circle. There is a closely related (and, for surface orders, even more canonical) way to generate "infinite-period" clocks: build a *tower of finite cyclic clocks* and pass to a limit. This picture appears naturally in the local-field/monodromy description of surface orders [37, 36].

Root towers at punctures and profinite cyclicity. Let x_j be a puncture (or ramification point) on a curve, with local field $F_j = \mathbb{C}((x_j))$. For each $n \geq 1$, adjoin an nth root of the local parameter to obtain an extension $F_j((x_j^{1/n}))$. There is a canonical cyclic subgroup of automorphisms generated by the rotation of the root,

$$x_j^{1/n} \longmapsto e^{2\pi i k/n} x_j^{1/n}, \qquad k \in \mathbb{Z}/n\mathbb{Z},$$

so $\mathrm{Gal}(F_j((x_j^{1/n}))/F_j) \cong \mathbb{Z}/n\mathbb{Z}$ in this elementary setting. Passing to the directed system $n \mid m$ produces an inductive limit containing all roots of unity, and dually produces the *procyclic completion*

$$\widehat{\mathbb{Z}} \cong \varprojlim_n \mathbb{Z}/n\mathbb{Z},$$

which is a canonical home for "clock phases" of arbitrarily large period.

Operator-algebraic packaging: odometers and solenoids. A standard ergodic model for $\widehat{\mathbb{Z}}$–structured time is the *adding machine* (odometer): a minimal uniquely ergodic action of $\mathbb{Z}$ on a Cantor space X_{Grn} built from the inverse limit of residue rings

$$X_{Grn} := \varprojlim_k \mathbb{Z}/n_k\mathbb{Z}, \qquad n_k \mid n_{k+1}.$$

The crossed product $C(X_{Grn}) \rtimes \mathbb{Z}$ is then an "inductive-limit clock algebra": it is an analytic completion of the observable algebra generated by *all* the finite clocks of periods n_k at once. For our purposes the key fact is the same as in Proposition 2.4: unique ergodicity provides a canonical invariant probability measure (Haar measure on the profinite group), hence a canonical trace state.

How irrational rotations arise from the tower. The procyclic tower is not the same object as A_θ (the rotation algebra is generated by a *single* irrational phase), but it is the correct device for implementing "irrational period" in hardware: choose convergents p_k/q_k of θ and set $n_k := q_k$. Then each level k supports a faithful q_k–dimensional projective representation of the rational noncommutative torus, generated by $(X_{q_k}, Z_{q_k}^{p_k})$, and the tower $q_k \mid q_{k+1}$ gives a coherent refinement ladder. In the limit (strong operator topology / inductive-limit sense), the spectrum of the refined clock becomes dense on S^1, and orbit averages converge to Haar/Lebesgue expectations by unique ergodicity.

2.7. Quantum-circuit implementation: nested cyclic qudits as irrational-rotation approximants. The tower picture can be made circuit-explicit while staying in the state-vector model.

Level-k clock register. Fix q_k and work on $\mathcal{H}_k \cong \mathbb{C}^{q_k}$ with basis $\{|j\rangle\}_{j\in\mathbb{Z}/q_k\mathbb{Z}}$. Implement

$$U_k := X_{q_k}, \qquad V_k := Z_{q_k}^{p_k}, \qquad \text{so that} \qquad V_k U_k = e^{2\pi i p_k/q_k} U_k V_k.$$

Both gates are native on qudit hardware; on qubits, U_k is modular addition by 1 and V_k is a diagonal phase gate.

Coherent refinement ("infinite period" limit register). Choose an embedding isometry $J_k : \mathcal{H}_k \hookrightarrow \mathcal{H}_{k+1}$ compatible with the residue map $\mathbb{Z}/q_{k+1}\mathbb{Z} \to \mathbb{Z}/q_k\mathbb{Z}$, so that $J_k U_k = U_{k+1} J_k$ and likewise for V_k up to a controlled phase that vanishes as $k \to \infty$ for good approximants. Then the direct limit Hilbert space $\mathcal{H}_\infty = \varinjlim(\mathcal{H}_k, J_k)$ carries limiting unitaries U_∞, V_∞ whose commutator phase is the target irrational $e^{2\pi i\theta}$ in the limit sense. Operationally: you never build $\mathcal{H}_\infty$ in hardware; you pick the level k needed for a given accuracy ϵ, using the Diophantine bound $|\theta - p_k/q_k| < 1/q_k^2$.

Validation checks (ergodic and spectral). The two simplest empirical diagnostics are:

(1) **Equidistribution / orbit tests:** for a fixed basis state, repeatedly apply U_k and measure in the V_k–eigenbasis; as k grows, the empirical distribution of phases should approach uniformity for "generic" initial states.

(2) **Commutator phase calibration:** estimate $\langle\psi|V_k U_k U_k^\dagger V_k^\dagger|\psi\rangle$ for random $|\psi\rangle$; it should concentrate near $e^{2\pi i p_k/q_k}$ and track the continued-fraction ladder as k is increased.

These are the circuit-level counterparts of the operator-algebraic statements above: unique ergodicity justifies replacing long-time orbit averages by trace-state expectations, which is exactly what later trace-formula / explicit-formula comparisons require.

3. Twisted shifts from orders (the valuation-aware successor)

In the order-theoretic layer (Chapter 2), the successor can acquire a uniformizer factor on wrap-around:

$$S_d(\pi) = \begin{pmatrix} 0 & 0 & \cdots & 0 & \pi \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \ddots & 0 & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix}, \qquad S_d(\pi)^d = \pi I_d.$$

Over a field extension adjoining a dth root $\pi^{1/d}$, the spectrum is $\pi^{1/d}\omega^k$. Projectively, the "clock" still has period d (up to central scaling), which is exactly the holonomy mechanism exploited later.

4. Infinite-dimensional clocks: the bilateral shift and continuous spectrum

Let $\mathcal{H} = \ell^2(\mathbb{Z})$ with basis $\{|n\rangle\}_{n\in\mathbb{Z}}$ and define the bilateral shift

$$(S|n\rangle) = |n+1\rangle.$$

Then S is unitary and has *continuous* spectrum equal to the unit circle. Under the Fourier transform $\ell^2(\mathbb{Z}) \cong L^2(S^1)$, S becomes multiplication by $e^{i\theta}$. A (non-unique) self-adjoint generator H can be chosen by functional calculus so that $S = e^{-iH}$ (Section 0.6).

5. From shifts to Hamiltonians: branch choices and physical units

If T is unitary, one may write $T = e^{-iH\Delta t/\hbar}$ for a self-adjoint (generally unbounded) H, but H is only determined up to adding integer multiples of $2\pi\hbar/\Delta t$ on spectral components. This *branch ambiguity* becomes a structural input when we glue local clocks: global consistency of branch choices is an additional holonomy constraint rather than a nuisance.

6. Implementation notes (quantum circuits)

For $d = 2^n$ (an n-qubit register), X_d is modular addition by 1 and can be implemented with a ripple-carry or QFT-based adder. For general d, one may either (i) embed $\mathbb{C}^d$ into a qubit register with unused states and post-select, or (ii) use native qudit hardware where the shift is a cyclic permutation gate. In all cases, hardware noise most strongly perturbs phase coherence; the persistence diagnostics in Chapter 6 are designed to be stable to such perturbations.

6.1. Beyond Clifford: learned controlled-U (CU) layers and universal gate sets. The circuit sketches in this manuscript sometimes mention Clifford layers because they are convenient for (i) randomized measurement and (ii) baseline stabilizer diagnostics. This should not be misread as a restriction of the dynamics to Clifford circuits. The renormalization layers are intended to be *learned* and therefore must include non-Clifford operations.

Controlled-U gates. A controlled-U (CU) gate on a control qubit and a d-level target is the unitary

$$\mathrm{CU}(U) = |0\rangle\langle 0| \otimes I_d + |1\rangle\langle 1| \otimes U,$$

and more generally on a qudit control one may condition on multiple control values. On an embedded graph/quiver, CU gates are canonical *edge-local entanglers*: place the control on one endpoint and the target on the adjacent endpoint.

Learnable edge gates and attention weights. In the QGCN/QGAT viewpoint (Sections 3–5), one may treat each edge $e = (u, v)$ as carrying a trainable two-site unitary

$$U_e(\theta_e) \in \mathrm{SU}(d_u d_v),$$

compiled into hardware primitives (often CU-like entanglers plus single-site rotations). In a graph-attention layer, the classical attention coefficient a_{uv} can modulate either (i) the angle of a controlled phase/rotation or (ii) the probability of applying a gate, yielding a stochastic quantum channel.

Why Clifford-only learning is a dead end. Clifford circuits are efficiently classically simulable and cannot densely explore $\mathrm{SU}(2^n)$. They are excellent for error mitigation and tomography primitives, but an emergent-geometry model requires genuinely non-Clifford entanglement generation. Pragmatically, one therefore uses:

- Clifford or approximate unitary 2-design layers for *measurement/tomography*, and
- learned CU/non-Clifford layers for *state preparation and dynamics*.

Density-operator phrasing. A learned unitary layer corresponds to the channel $\rho \mapsto U(\theta)\rho U(\theta)^\dagger$, optionally composed with noise. This is the language used in Section 7 when reduced density operators are mapped to modular Hamiltonians.

7. Circuit dynamics as quantum channels and density operators

The discussion above used state vectors $|\psi\rangle$ for clarity, but most of the program—especially the parts that are meant to survive hardware noise, mid-circuit measurements, and coarse-graining—is more naturally phrased in terms of *density operators*. We record the translation explicitly so later chapters (modular Hamiltonians, renormalization channels, and the Hilbert–Pólya trace identities) can reuse it without ambiguity.

7.1. Pure states, mixed states, and expectations. A (finite-dimensional) *density operator* on a Hilbert space $\mathcal{H}$ is an operator $\rho \in \mathcal{B}(\mathcal{H})$ such that $\rho \geq 0$ and $\mathrm{Tr}(\rho) = 1$. Pure states are rank-one projectors $\rho = |\psi\rangle\langle\psi|$, while mixtures have $\mathrm{rank}(\rho) > 1$.

For any observable $O = O^\dagger$ the expectation value is

$$\langle O\rangle_\rho := \mathrm{Tr}(\rho\, O),$$

which reduces to $\langle\psi|O|\psi\rangle$ in the pure case.

If the register splits as $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_{A^c}$, the reduced state on A is

$$\rho_A := \mathrm{Tr}_{A^c}(\rho).$$

All information-theoretic quantities used later (entropies, mutual information, modular Hamiltonians) are functions of such reduced density operators. In particular, the mutual information proxy $I(A:B)$ used as a weight in persistence is a functional of $(\rho_A, \rho_B, \rho_{AB})$ and is therefore insensitive to global phases and robust under mixing.

7.2. Gates, noise, and measurements as CPTP maps. An ideal unitary gate U acts on density operators by conjugation,

$$\rho \longmapsto \mathcal{U}(\rho) := U\rho U^\dagger.$$

Hardware noise, measurements, and classical conditioning are captured by *quantum channels*: completely positive trace-preserving (CPTP) maps

$$\mathcal{E} : \mathcal{B}(\mathcal{H}) \to \mathcal{B}(\mathcal{H}').$$

In Kraus form,

$$\mathcal{E}(\rho) = \sum_a K_a \rho K_a^\dagger, \qquad \sum_a K_a^\dagger K_a = I. \tag{7.1}$$

The post-selected (unnormalized) state for outcome a is $K_a \rho K_a^\dagger$, and the corresponding outcome probability is $\mathrm{Tr}(K_a \rho K_a^\dagger)$.

7.2.1. *Measurement as entanglement and phase transfer in open quantum systems.* The Kraus formula (7.1) is already the mathematically correct way to talk about measurement in an open system, but it can feel "black-box". To avoid the misleading image of "projectors from nowhere", recall the Stinespring dilation theorem: every CPTP map arises from a unitary interaction with an ancilla (environment) followed by a partial trace.

Projective measurement from a unitary premeasurement. Let $\{P_a\}_a$ be an orthogonal projector-valued measure on $\mathcal{H}_S$ and let $\mathcal{H}_M$ be a meter with pointer basis $\{|a\rangle_M\}_a$. Define a unitary U on $S \otimes M$ by

$$U\big(|\psi\rangle_S \otimes |0\rangle_M\big) = \sum_a (P_a|\psi\rangle_S) \otimes |a\rangle_M.$$

For an input density operator ρ the joint post-interaction state is $U(\rho \otimes |0\rangle\langle 0|)U^\dagger$ and the reduced state on S is

$$\rho \longmapsto \mathrm{Tr}_M\Big(U(\rho \otimes |0\rangle\langle 0|)U^\dagger\Big) = \sum_a P_a \rho P_a,$$

which is exactly the usual Lüders update channel. Conditioning on the classical record a yields the normalized state $\rho_a = P_a \rho P_a / \mathrm{Tr}(P_a \rho)$. Thus the projector update is the reduced description of an entangling unitary plus discarding/conditioning, not an extra physical axiom [59, 60].

Local phases become global branch phases. If $|\psi\rangle = \sum_a c_a |a\rangle$ in an eigenbasis of the measured observable, then the premeasurement state is

$$|\Psi\rangle_{SM} = \sum_a c_a\, |a\rangle_S \otimes |a\rangle_M.$$

A global phase of $|\Psi\rangle_{SM}$ is physically irrelevant, but the relative phases of the coefficients c_a now live in the *relative phase between different entangled branches*. When the meter/environment decoheres (or is traced out), the off-diagonal terms in ρ_S disappear and those phases become operationally inaccessible on S alone. In this sense, "measurement" transfers local phase information into a global, environment-correlated phase record.

POVMs and instruments. The same construction holds for general POVMs: given Kraus operators $\{K_a\}$, there exists an ancilla and a unitary U such that $K_a = \langle a|U|0\rangle$. The family $\rho \mapsto K_a \rho K_a^\dagger$ is a quantum instrument; summing over a gives the unconditional CPTP map [61].

We will use this viewpoint repeatedly: pooling/renormalization steps are partial traces (discarding degrees of freedom), while measurement corresponds to partial trace *plus* retaining a classical record of the discarded subsystem.

A depth-L circuit with interleaved noise is therefore a channel composition

$$\rho_{\mathrm{out}} = (\mathcal{E}_L \circ \cdots \circ \mathcal{E}_1)(\rho_{\mathrm{in}}).$$

This viewpoint is essential for two reasons: (i) it makes clear which features of the construction are stable under decoherence, and (ii) it is the natural language for renormalization, where discarding degrees of freedom is literally a partial trace.

7.3. Shift/clock primitives as channel building blocks. For a cyclic qudit $\mathcal{H}_d$, the shift and clock unitaries X_d, Z_d act on density operators by

$$\rho \mapsto X_d \rho X_d^\dagger, \qquad \rho \mapsto Z_d \rho Z_d^\dagger.$$

A coherent superposition of ticks is a state with nonzero off-diagonal terms in the Z_d-basis; phase noise (dephasing) is the channel

$$\mathcal{D}_p(\rho) = (1-p)\rho + p \sum_{k \in \mathbb{Z}_d} |k\rangle\langle k|\rho|k\rangle\langle k|,$$

which kills those off-diagonal terms. This is precisely why the persistence diagnostics in Chapter 6 are built to tolerate loss of phase coherence: they are defined on *reduced density operators* and on invariants (entropies, mutual informations, correlation functions) that make sense for mixed states.

7.4. From unitary "ticks" to open-system generators. If T is a perfect unitary tick, the Hamiltonian-log construction $T = e^{-iH\Delta t/\hbar}$ lives on the unitary group. For noisy ticks, one instead has a channel $\mathcal{E}$ per tick, and the infinitesimal generator is a *Liouvillian* superoperator $\mathcal{L}$ with

$$\mathcal{E} \approx e^{\Delta t\, \mathcal{L}}, \qquad \dot{\rho} = \mathcal{L}(\rho).$$

In the Markovian setting, $\mathcal{L}$ has Lindblad form

$$\mathcal{L}(\rho) = -\frac{i}{\hbar}[H, \rho] + \sum_j \Big(L_j \rho L_j^\dagger - \frac{1}{2}\{L_j^\dagger L_j, \rho\} \Big). \tag{7.2}$$

The same branch issues appear when taking a logarithm of $\mathcal{E}$: one must choose a branch for the spectrum of the superoperator on the complex unit disk, and gluing local choices becomes a holonomy constraint in the space of channels. This is the open-system analogue of the branch ambiguity discussed earlier for $T = e^{-iH\Delta t/\hbar}$.

CHAPTER 18

Gluing local orders into global time holonomy

The main body sketches the slogan:

local shifts glue to a global holonomy, and cyclic time is torsion holonomy.

This chapter replaces the slogan by a concrete (and, crucially, *cohomological*) framework.

0.1. Orders as local operator algebras: sheaf language. Let X be an oriented surface (topological, smooth, or Riemann, depending on context). A *surface order* in the sense of the text is best regarded as a sheaf (or stack) of algebras on X whose stalks are local matrix orders.

For this chapter we work in a simplified but robust model:

(1) Cover X by open sets $\{U_i\}$ such that on each U_i the order is isomorphic to a fixed hereditary order $\Lambda_{m_i}(R_i)$ as in (2.1).

(2) On overlaps $U_{ij} = U_i \cap U_j$, glue by algebra isomorphisms

$$g_{ij} : \Lambda|_{U_{ij}} \xrightarrow{\sim} \Lambda|_{U_{ij}}$$

satisfying the cocycle condition $g_{ij}g_{jk}g_{ki} = \mathrm{id}$ on triple overlaps.

Definition 0.1 (Gluing cocycle). The collection $\{g_{ij}\}$ is a Čech 1–cocycle with values in the sheaf of groups $\mathrm{Aut}(\Lambda)$, hence defines a class

$$[g] \in \check{H}^1(X; \mathrm{Aut}(\Lambda)).$$

Remark 0.2 (Why cohomology is the right bookkeeping). The moment we say "holonomy", we have already committed to the fact that local data is not globally exact. Cohomology is precisely the formal language of "locally exact, globally twisted".

0.2. Clock data as a normalizer-valued field. On each chart U_i (typically centered at a vertex of the embedded graph), choose a *clock operator*

$$S_i \in N_{\mathrm{GL}_{m_i}(K_i)}(\Lambda_{m_i}(R_i)),$$

where $N(\cdot)$ denotes the normalizer. In the cleanest hereditary situation we take $S_i = S_{m_i}(\pi_i)$ from (2.2).

The physical meaning is: S_i is a distinguished local unitary (or projective unitary) generating the local "tick" symmetry. The mathematical meaning is: S_i is an element with conjugation action that preserves the local order, hence is compatible with gluing.

Definition 0.3 (Clocked surface order). A *clocked surface order* is a pair (Λ, S) where Λ is a surface order and $S = \{S_i\}$ is a choice of normalizer elements on a cover, subject to the compatibility condition

$$S_j = g_{ij} S_i g_{ij}^{-1} \qquad \text{on } U_{ij}.$$

Compatibility says exactly that "clock operators glue as a section of a twisted bundle".

0.3. Holonomy as a representation of the fundamental group. Given the cocycle data, we can extract holonomy along loops.

Fix a basepoint $x \in X$ and a loop γ represented by a chain of overlaps

$$U_{i_0} \supset U_{i_0 i_1} \supset U_{i_1} \supset \cdots \supset U_{i_{n-1} i_n} \supset U_{i_n} = U_{i_0}.$$

Define the holonomy element

$$\mathrm{Hol}_g(\gamma) := g_{i_0 i_1} g_{i_1 i_2} \cdots g_{i_{n-1} i_n} \in \mathrm{Aut}(\Lambda_x).$$

Proposition 0.4. *Up to conjugacy,* $\mathrm{Hol}_g(\gamma)$ *depends only on the homotopy class* $[\gamma] \in \pi_1(X, x)$*, and the map*

$$\mathrm{Hol}_g : \pi_1(X, x) \to \mathrm{Out}(\Lambda_x)$$

is a group homomorphism.

Proof. Standard Čech-to-fundamental-group correspondence: refining covers and changing representatives corresponds to inserting cancelling pairs $g_{ij} g_{ji} = \mathrm{id}$. Dependence on basepoint yields conjugacy. □

Remark 0.5 (The correct target). For physics, global time is a projective concept: conjugation by a local unitary is gauge. Thus the natural target is an *outer* automorphism group, or projective normalizers. This aligns with Proposition 2.3, where the projective class of a twisted shift is torsion even if the linear class is not.

0.4. Time holonomy: gluing the clock field. When the clock field S is compatible with the cocycle, it becomes meaningful to transport S around a loop.

Let S_{i_0} be the clock operator in the chart containing the basepoint. Transporting it around γ produces

$$S_{i_0} \longmapsto \mathrm{Hol}_g(\gamma)\, S_{i_0}\, \mathrm{Hol}_g(\gamma)^{-1}.$$

If this equals S_{i_0}, the loop preserves the clock; if not, the loop changes clock phase/rate.

This motivates the operational definition:

Definition 0.6 (Time holonomy subgroup). The *time holonomy subgroup* is the subgroup

$$\mathcal{H}_{\text{time}} := \{\mathrm{Hol}_g(\gamma) \in \mathrm{Out}(\Lambda_x) \ : \ \gamma \in \pi_1(X)\}.$$

Definition 0.7 (Cyclic time and projective cyclic time). We say the clocked order has:

- *cyclic time* if $\mathcal{H}_{\text{time}}$ is finite;
- *projectively cyclic time* if the induced subgroup in a projective quotient (e.g. PGL or Out/center) is finite.

Projective cyclicity is the robust notion when local twisted shifts satisfy $S^m = \pi I$.

0.5. Explicit gluing: pants → torus and the holonomy operator. We now make the "IKEA" comment in §3.7 mathematically concrete.

Consider a pair of pants P with boundary components C_1, C_2, C_3. Assign to each boundary component a local clock algebra with shift S_i (finite or infinite). Gluing C_1 to C_2 produces a surface T with one boundary component (a once-punctured torus). The gluing identifies the corresponding idempotents and imposes a constraint that the boundary shifts are inverses up to conjugacy:

$$S_2 \sim g S_1^{-1} g^{-1}$$

for a gluing element g determined by the identification.

Proposition 0.8 (Holonomy on the glued handle). *Let α be the core loop of the handle created by gluing C_1 to C_2. Then the time holonomy along α is represented (up to conjugacy) by the product*

$$H_\alpha \ \sim \ S_1\, g\, S_2\, g^{-1}.$$

If $S_2 \sim gS_1^{-1}g^{-1}$ exactly, then H_α is central. If S_1 and S_2 are twisted shifts, centrality yields a π–power in the center.

Proof sketch. Track the clock operator around the handle: traverse boundary C_1 (apply S_1), cross the seam (apply g), traverse C_2 (apply S_2), cross back (apply g^{-1}). □

Remark 0.9 (Where gravity enters). If entanglement changes the effective local valuation parameters π_i (see Section 23), then even when the topological gluing is fixed, the holonomy can drift from torsion to non-torsion. This is the clean conceptual place where "more entanglement ⇒ slower time" can be encoded: increased entanglement modifies the local clock generator, which changes holonomy spectra.

0.6. Nilpotent/unipotent truncations as bounded drift. The main body proposes nilpotent/unipotent truncations to model "almost cyclic" time (Part V). We record a minimal algebraic model that interacts nicely with gluing cocycles.

Definition 0.10 (Unipotent truncation). Fix $N \geq 1$ and define the unipotent quotient of the Laurent polynomial algebra

$$k[t, t^{-1}] \twoheadrightarrow k[t, t^{-1}]/(t-1)^N.$$

The image of t acts as a unipotent operator $U = 1 + J$ with $J^N = 0$.

Proposition 0.11. *If each local clock generator is unipotent of order N in the above sense, then the holonomy subgroup $\mathcal{H}_{\text{time}}$ is nilpotent-by-finite: its image in the semisimple quotient is finite, and its kernel is a nilpotent group of exponent bounded by N (in typical finite-dimensional realizations).*

Remark 0.12. This proposition formalizes what the physics language calls "bounded drift": time may not close exactly, but its failure to close is polynomially controlled.

0.7. Cohomological obstructions and a practical checklist. For the reader trying to implement the theory (either mathematically or on hardware), it is useful to isolate three checkable conditions.

(1) **Local normalizer condition:** each intended clock operator S_i must normalize the local order; in hereditary models this is Lemma 2.2.
(2) **Cocycle consistency:** gluing maps must satisfy the Čech cocycle condition; failure indicates an inconsistent surface order (or an overlooked orbifold point).
(3) **Holonomy classification:** compute $\mathrm{Hol}_g(\gamma)$ on a generating set of $\pi_1(X)$. Cyclic time corresponds to finiteness (or projective finiteness) of the generated subgroup.

These are the exact places where multiparameter persistence becomes useful: when the cocycle data is derived from noisy/estimated entanglement measurements, one expects *stability* of the induced holonomy class under controlled perturbations. Section 6 turns this into computable invariants.

CHAPTER 19

Hyperbolic surfaces, quotients, and why infinite covers are structurally unavoidable

The main body motivates hyperbolic quotients briefly (§6.7), mainly to justify why $\mathbb{Z}$–indexed (infinite-cyclic) clocks appear naturally. This chapter expands that discussion in a way that is intended to be *mathematically checkable*.

0.1. The hyperbolic plane as the universal local model. We use the upper half-plane model

$$\mathbb{H} = \{z = x + iy \in \mathbb{C} : y > 0\}$$

with hyperbolic metric

$$ds^2 = \frac{dx^2 + dy^2}{y^2}. \tag{0.1}$$

The group $\mathrm{PSL}(2, \mathbb{R})$ acts by Möbius transformations

$$z \longmapsto \frac{az + b}{cz + d}, \qquad \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{PSL}(2, \mathbb{R}),$$

and this action is by orientation-preserving isometries of (0.1).

Definition 0.1 (Fuchsian group). A *Fuchsian group* is a discrete subgroup $\Gamma \leq \mathrm{PSL}(2, \mathbb{R})$. The quotient $\mathbb{H}/\Gamma$ is a (possibly orbifold) hyperbolic surface; it has finite area if and only if Γ is a lattice.

The basic structural fact we will repeatedly use is that *every hyperbolic surface is a quotient of* $\mathbb{H}$. The "local-to-global" mechanism in this volume is an algebraic analogue: local vertex orders behave like "charts", and gluing data behaves like a discrete connection whose holonomy lives in an automorphism group.

0.2. Triangle groups, constellations, and dessins as quotients. A recurrent constellation in the source material is the (p, q, r) triangle-group presentation

$$\Delta(p, q, r) = \langle \gamma_0, \gamma_1, \gamma_\infty \mid \gamma_0^p = \gamma_1^q = \gamma_\infty^r = \gamma_0\gamma_1\gamma_\infty = 1 \rangle. \tag{0.2}$$

As noted in the source text reproduced in Appendix A of the volume, this is one natural bridge between permutation (dessin) data and hyperbolic orbifolds.

Proposition 0.2 (From dessins to orbifold quotients (sketch-level)). *Let $(\sigma_0, \sigma_1, \sigma_\infty)$ be a transitive permutation triple with $\sigma_0\sigma_1\sigma_\infty = 1$. Then there is a finite-index subgroup $\Gamma \leq \Delta(p, q, r)$ (for suitable (p, q, r) determined by cycle lengths) and a branched covering map*

$$f : \mathbb{H}/\Gamma \to \mathbb{H}/\Delta(p, q, r) \cong \mathbb{P}^1(\mathbb{C})$$

ramified only above three orbifold points.

Remark 0.3. This proposition is a modern restatement of the fact that dessins are equivalent to Belyi maps. We *do not* need arithmetic in order to use the quotient geometry; what we need is the existence of a hyperbolic universal cover and a discrete group acting with controlled stabilizers.

The reason hyperbolic quotients belong in the present theory is not only "because modular curves exist", but because they provide *canonical infinite cellulations* (e.g. Farey tessellation) whose deck actions realize the $\mathbb{Z}$–type shifts that later become clock operators.

0.3. Cellulations, ribbon graphs, and induced quivers on $\mathbb{H}/\Gamma$. Fix a finite-area hyperbolic surface (or orbifold) $X = \mathbb{H}/\Gamma$. A standard way to put combinatorics on X is:

(1) pick a Γ–invariant tessellation $\mathcal{T}$ of $\mathbb{H}$ by ideal polygons (or by geodesic triangles);
(2) descend $\mathcal{T}$ to a finite (or locally finite) cell structure on X.

The *directed medial quiver* construction (used heavily in the surface-algebra material presented in earlier sections) applies verbatim to any oriented cellulation: for each face, run arrows along medial vertices counterclockwise.

Definition 0.4 (Locally finite surface algebra from a hyperbolic cellulation). Let $\mathcal{T}$ be a locally finite, oriented cellulation of $\mathbb{H}$ invariant under Γ. Let $Q(\mathcal{T})$ be its directed medial quiver. Define the *hyperbolic surface algebra* as the completed path algebra

$$A(\mathcal{T}) := k\langle\langle Q_1 \rangle\rangle / I,$$

where I is a gentle-style ideal generated by length-2 forbidden turns determined by the local incidence constraints of $\mathcal{T}$.

Because $\mathcal{T}$ is infinite on $\mathbb{H}$, $Q(\mathcal{T})$ is infinite and the completion is not optional. Finite quotients correspond to taking Γ' of finite index and passing to $X' = \mathbb{H}/\Gamma'$; the quiver becomes finite if the quotient cellulation is finite.

0.4. Why $\mathbb{Z}$–indexed clocks appear: deck transformations as time translations. The text already defines an infinite-cyclic qudit as $\ell^2(\mathbb{Z})$ with bilateral shift $T|n\rangle = |n+1\rangle$ (§3.5). Here is the geometric reason this is the *correct* representation-theoretic object.

Definition 0.5 (Winding number cocycle). Let $X = \mathbb{H}/\Gamma$ be a surface with at least one essential loop $\alpha \in \pi_1(X)$. Fix a basepoint and identify $\pi_1(X)$ with a subgroup of deck transformations of $\mathbb{H}$. For a chosen embedded graph $\Gamma_0 \subset X$ inducing a cellulation, define a function

$$w : \pi_1(X) \to \mathbb{Z}$$

by taking a lift of α to $\mathbb{H}$ and counting algebraically how many times it crosses a chosen fundamental cycle in the lift of Γ_0.

This is a $\mathbb{Z}$–valued group 1–cocycle in the sense that $w(\alpha\beta) = w(\alpha) + w(\beta)$. It therefore gives a unitary representation of the $\mathbb{Z}$–quotient of $\pi_1(X)$ on $\ell^2(\mathbb{Z})$ by shifts.

Proposition 0.6 (Deck-action representation yields the bilateral shift). *Let $\langle t \rangle \cong \mathbb{Z}$ be a cyclic quotient of $\pi_1(X)$ detected by a winding cocycle w. Then the induced representation on $\ell^2(\mathbb{Z})$ satisfies*

$$\rho(t)|n\rangle = |n+1\rangle,$$

i.e. $\rho(t)$ is the bilateral shift.

Proof. Represent t by a deck transformation that advances the lift of the fundamental cycle by one. The basis vector $|n\rangle$ is identified with the n-th translate of a chosen reference tile in $\mathbb{H}$. Applying t moves the reference tile forward by one translate, hence $|n\rangle \mapsto |n+1\rangle$. □

Remark 0.7 (Finite vs infinite time). Finite d–qudits arise precisely when the relevant deck action is *torsion in an appropriate quotient*—for example, after passing to a finite cover and quotienting by a period.

The twisted-shift relation $S_m(\pi)^m = \pi I$ (Proposition 2.3) is an algebraic analogue: time is cyclic *projectively* even if not cyclic in GL.

0.5. Hyperbolic distance, combinatorial distance, and entanglement distance. The emergent-geometry layer of the text assigns an entanglement-derived weight $w_\psi(u, v)$ on edges and builds an effective distance d_ψ (Chapter 7). On a hyperbolic surface we have three conceptually distinct distances:

(1) d_{hyp}: the intrinsic hyperbolic geodesic distance on X,

(2) d_{comb}: the graph metric on the 1–skeleton of a chosen cellulation,

(3) d_ψ: an information-theoretic metric (or pseudometric) induced by a quantum state.

A coherent continuum-limit story must control the relationships among them.

Proposition 0.8 (Quasi-isometry of hyperbolic and combinatorial metrics). *Let X be a finite-area hyperbolic surface and $\mathcal{T}$ a finite-type geodesic triangulation with bounded geometry (uniform bounds on edge lengths and angles). Then (X, d_{hyp}) is quasi-isometric to the 1–skeleton $(\mathcal{T}^{(1)}, d_{\text{comb}})$.*

Proof sketch. Standard in geometric group theory: bounded-geometry triangulations give uniform bilipschitz control between piecewise-geodesic paths along edges and true geodesics. □

Definition 0.9 (Entanglement distance from mutual information). Fix a state $|\psi\rangle$ on a graph of local algebras. For vertices u, v define a weight $I(u:v)$ (e.g. mutual information or a Renyi proxy) and set

$$\ell_\psi(u, v) := \max\{0, -\log(I(u:v)/I_0)\},$$

where I_0 is a reference scale making the logarithm dimensionless. Define d_ψ as the shortest-path metric with edge lengths ℓ_ψ.

Remark 0.10 (Units). Mutual information is measured in *bits* (or nats), hence dimensionless. The logarithm therefore produces a dimensionless length. To compare to d_{hyp} one must insert a length scale ℓ_* (e.g. average edge length of the cellulation): $d_\psi^{\text{phys}} = \ell_* \, d_\psi$.

The mathematical burden of the emergent-gravity program is now clear: one needs conditions under which d_ψ becomes quasi-isometric to d_{comb} (and hence to d_{hyp}) in a scaling limit. Section 6 makes this quantitative using multiparameter persistence stability.

0.6. A worked hyperbolic example: modular tessellations and quotient dessins. The modular group $\mathrm{PSL}(2, \mathbb{Z})$ acts on $\mathbb{H}$ with fundamental domain a hyperbolic triangle of angles $(0, \pi/3, \pi/2)$. The Farey tessellation is a $\mathrm{PSL}(2, \mathbb{Z})$–invariant ideal triangulation of $\mathbb{H}$. Finite-index subgroups $\Gamma \leq \mathrm{PSL}(2, \mathbb{Z})$ yield quotient surfaces (modular curves) equipped with descended triangulations, and these quotients can be encoded combinatorially as dessins/hypermaps.

For our purposes, the key point is:

> *Modular quotients provide a canonical laboratory where (i) surface orders have arithmetic meaning, (ii) cellulations are hyperbolic, and (iii) deck actions are explicit.*

In Section 24 we use this to propose concrete numerical tests for a Hilbert–Pólya-style spectral program: modular surfaces give operators with trace formulas, while surface-order clocks supply natural internal shifts that can be coupled to those operators.

CHAPTER 20

Entanglement → metric → Einstein limit: a deeper modeling layer

One remarkable feature of quantum systems is that entanglement structure can be converted into geometric data: by quantifying correlations between subsystems, one obtains distance metrics on graphs, and these metrics can exhibit features reminiscent of gravitational geometry. This chapter makes this correspondence precise and explores how the clocked surface-order framework can naturally produce emergent Einstein-like equations.

The main body (Chapter 7) introduces an emergent-gravity dictionary based on entanglement-induced distances on graphs and a qualitative redshift mechanism. This chapter expands the physics/mathematics interface in a way that is compatible with the surface-order and persistence machinery developed earlier.

0.1. Indication → guidepost → endpoint (the experimental posture). Because "emergent gravity" is a large claim, it is useful to phrase the program as an indication/guidepost/endpoint pipeline:

- **Indication:** Does a clocked surface-order system exhibit an operational redshift: locally defined clock rates depend on a state-dependent "gravitational potential"?
- **Guidepost:** A stable, state-dependent metric-like object (distance matrix or graph metric) extracted from entanglement, whose curvature-like summaries vary predictably with entanglement gradients.
- **Endpoint:** In a refinement/coarse-graining limit, do these metric-like objects converge (in a precise sense) to a smooth Lorentzian/Riemannian metric satisfying Einstein-like equations?

The purpose of multiparameter persistence (Section 6) is to make the *guidepost* stable and computable; the purpose of surface orders is to make the *indication* structurally constrained by gluing/holonomy.

0.2. From entanglement to an effective metric: assumptions and definitions. Let Γ be an embedded graph with vertices V and edges E. Let $|\psi\rangle$ be a state on $\bigotimes_{v\in V}\mathcal{H}_v$.

0.2.1. *Assumption A (locality).* We assume correlations decay with graph distance in the absence of special structure. Operationally: $I(u:v)$ is largest for u, v near each other in d_{comb}.

0.2.2. *Assumption B (monotone length assignment).* Choose a monotone map from correlation to edge length. A canonical family is:

$$\ell_\psi(u,v) = \ell_*\, f(I(u:v))\,, \qquad f' < 0, \tag{0.1}$$

where ℓ_* is a physical length scale.

The simple logarithmic choice used earlier is $f(I) = -\log(I/I_0)$; alternatives include $f(I) = I^{-1}$ or soft-thresholded versions to handle noise.

0.2.3. *Path metric.* Define the induced path metric

$$d_\psi(u,v) = \inf_{\gamma:u\to v} \sum_{(a,b)\in\gamma} \ell_\psi(a,b).$$

Lemma 0.1 (Metric well-posedness). *If $\ell_\psi(u,v) > 0$ on edges and ℓ_ψ is symmetric, then d_ψ is a metric on each connected component of Γ. If some edges have $\ell_\psi = 0$ (perfect correlation), d_ψ is a pseudometric.*

0.3. Curvature surrogates on graphs. A metric on a discrete set does not automatically yield curvature. There are multiple curvature notions in discrete geometry (Ollivier–Ricci, Forman curvature, angle defects in triangulations). For surface-embedded graphs there is a particularly natural choice.

0.3.1. *Angle defect curvature for embedded triangulations.* Assume Γ is the 1-skeleton of a triangulation. Assign an *effective edge length* ℓ_ψ and define triangle angles via Euclidean or hyperbolic cosine laws (depending on target geometry). Then at a vertex v, define the angle defect

$$\kappa_\psi(v) := 2\pi - \sum_{\triangle \ni v} \theta_\triangle(v).$$

This is a discrete Gauss curvature.

Remark 0.2 (Target geometry choice). If the underlying surface is hyperbolic (Section 19), using hyperbolic triangle laws is natural. If one aims for an emergent Lorentzian picture, one instead works with causal diamonds and modular Hamiltonians; we return to this below.

0.3.2. *Ollivier–Ricci as a metric-only surrogate.* When only a metric is available (no embedding), Ollivier–Ricci curvature is defined by comparing Wasserstein distances between neighborhood measures. This is computationally expensive at 10^4 vertices but feasible on local patches.

0.4. Relational time, modular flow, and the redshift mechanism. In operator-algebraic language, a region A has reduced state ρ_A and modular Hamiltonian $K_A = -\log \rho_A$. Modular flow

$$\sigma_A^t(O) = e^{itK_A} O e^{-itK_A}$$

is a canonical dynamics *intrinsic* to the state.

The program's clock operators S_v supply a *kinematic* time basis. Entanglement then modifies how the state explores that basis. A minimal phenomenological model is:

Definition 0.3 (Clock rate functional). Fix a local clock observable N_v (e.g. the "position" basis index) and define clock rate at v by

$$r_v := \frac{d}{dt}\langle N_v \rangle_{\psi(t)}$$

under a chosen global evolution (circuit layer, modular flow, or physical Hamiltonian).

0.4.1. *Redshift ansatz.* Let ε_v be an entanglement density proxy, for instance

$$\varepsilon_v := \frac{1}{\deg(v)} \sum_{u \sim v} I(v:u).$$

Postulate

$$r_v \approx r_0\, e^{-\alpha \varepsilon_v}. \tag{0.2}$$

For small $\alpha\varepsilon_v$, $r_v \approx r_0(1 - \alpha\varepsilon_v)$.

Remark 0.4 (Units). r_v has units of inverse time. ε_v is dimensionless (bits). Therefore α has units of inverse bits. To compare to GR redshift $d\tau = \sqrt{-g_{tt}}\, dt \approx (1 - \Phi/c^2)dt$, we interpret

$$\Phi_v/c^2 \;\sim\; \alpha\, \varepsilon_v.$$

Thus Φ_v (potential) is proportional to entanglement density, with proportionality constant $c^2\alpha$.

0.5. Modular Hamiltonians, relative entropy, and finite-dimensional proofs. The modular Hamiltonian $K_A = -\log \rho_A$ is the correct *operator* object that packages both entanglement and an intrinsic notion of time. Because the present framework is discretized (finite-dimensional on each patch), we can be explicit and prove the standard entanglement "first law" statements directly in matrix-analysis terms, without field-theoretic subtleties.

0.5.1. *Definition, support, and a practical regularization.* If ρ_A is full rank, then K_A is a bounded self-adjoint operator with spectral decomposition

$$\rho_A = \sum_i p_i |i\rangle\langle i|, \qquad p_i > 0, \quad \sum_i p_i = 1,$$

$$K_A = -\log \rho_A = \sum_i (-\log p_i)|i\rangle\langle i|.$$

If ρ_A has zero eigenvalues, the logarithm diverges. Conceptually one works on the support $\mathrm{supp}(\rho_A)$; numerically, a stable regularization is

$$\rho_A^{(\epsilon)} := (1-\epsilon)\rho_A + \epsilon \frac{I}{\dim \mathcal{H}_A}, \qquad K_A^{(\epsilon)} := -\log \rho_A^{(\epsilon)}, \tag{0.3}$$

with $\epsilon \downarrow 0$. All statements below remain valid under this regularization provided variations stay within the support in the $\epsilon \to 0$ limit.

0.5.2. *Relative entropy positivity (a finite-dimensional proof).* For states $\rho, \sigma \geq 0$ with $\mathrm{Tr}\,\rho = \mathrm{Tr}\,\sigma = 1$, the (Umegaki) quantum relative entropy is

$$S(\rho\|\sigma) := \mathrm{Tr}\big(\rho(\log\rho - \log\sigma)\big),$$

with the convention $S(\rho\|\sigma) = +\infty$ if $\mathrm{supp}(\rho) \not\subseteq \mathrm{supp}(\sigma)$.

Proposition 0.5 (Positivity of relative entropy). *For density operators ρ, σ on a finite-dimensional Hilbert space,*

$$S(\rho\|\sigma) \geq 0,$$

with equality iff $\rho = \sigma$.

Proof. Assume first that ρ and σ are full rank (otherwise use the regularization (0.3) and continuity on the common support). For $\alpha \in (0,1)$ define the Petz–Rényi divergence

$$D_\alpha(\rho\|\sigma) := \frac{1}{\alpha - 1} \log \mathrm{Tr}(\rho^\alpha \sigma^{1-\alpha}).$$

By Hölder's inequality for Schatten norms,

$$\mathrm{Tr}(\rho^\alpha\sigma^{1-\alpha}) \leq \|\rho^\alpha\|_{1/\alpha}\, \|\sigma^{1-\alpha}\|_{1/(1-\alpha)} = (\mathrm{Tr}\,\rho)^\alpha\, (\mathrm{Tr}\,\sigma)^{1-\alpha} = 1.$$

Hence $\log \mathrm{Tr}(\rho^\alpha\sigma^{1-\alpha}) \leq 0$, and since $\alpha - 1 < 0$ it follows that $D_\alpha(\rho\|\sigma) \geq 0$ for all $\alpha \in (0,1)$.

Finally, the limit $\alpha \uparrow 1$ recovers the Umegaki relative entropy: using $\frac{d}{d\alpha}\rho^\alpha = \rho^\alpha \log\rho$ and $\frac{d}{d\alpha}\sigma^{1-\alpha} = -\sigma^{1-\alpha}\log\sigma$, one checks

$$\frac{d}{d\alpha}\,\mathrm{Tr}(\rho^\alpha\sigma^{1-\alpha})\Big|_{\alpha=1} = \mathrm{Tr}\big(\rho(\log\rho - \log\sigma)\big) = S(\rho\|\sigma),$$

and L'Hospital's rule yields $\lim_{\alpha\uparrow 1} D_\alpha(\rho\|\sigma) = S(\rho\|\sigma)$. Therefore $S(\rho\|\sigma) \geq 0$.

Equality holds only if Hölder's inequality is tight, which forces ρ^α and $\sigma^{1-\alpha}$ to be proportional in Schatten norm for some $\alpha \in (0,1)$, hence $\rho = \sigma$ after normalization. □

0.5.3. *First law of entanglement as a corollary.* Fix a full-rank reference state σ and consider a differentiable curve of states $\rho(\epsilon)$ with $\rho(0) = \sigma$ and $\mathrm{Tr}(\rho(\epsilon)) = 1$. Since $S(\rho(\epsilon)\|\sigma) \geq 0$ with equality at $\epsilon = 0$, we have $\frac{d}{d\epsilon} S(\rho(\epsilon)\|\sigma)\big|_{\epsilon=0} = 0$. Writing out the derivative gives the entanglement "first law":

Corollary 0.6 (First law of entanglement). *Let σ be full rank and $\rho(\epsilon)$ a differentiable curve with $\rho(0) = \sigma$. Then*

$$\frac{d}{d\epsilon} S(\rho(\epsilon))\Big|_{\epsilon=0} = \frac{d}{d\epsilon}\,\mathrm{Tr}(\rho(\epsilon)\,K_\sigma)\Big|_{\epsilon=0}, \qquad K_\sigma := -\log\sigma,$$

where $S(\rho) = -\mathrm{Tr}(\rho\log\rho)$ is the von Neumann entropy.

Proof. Differentiate $S(\rho(\epsilon)\|\sigma) = \mathrm{Tr}(\rho(\epsilon)(\log\rho(\epsilon) - \log\sigma))$ at $\epsilon = 0$. The derivative of $\mathrm{Tr}(\rho(\epsilon)\log\rho(\epsilon))$ at $\epsilon = 0$ equals $\mathrm{Tr}(\rho'(0)(\log\sigma + I))$ (Fréchet derivative of $\rho \mapsto \mathrm{Tr}(\rho\log\rho)$), and $\mathrm{Tr}(\rho'(0)) = 0$. Thus

$$0 = \frac{d}{d\epsilon}S(\rho(\epsilon)\|\sigma)\bigg|_{\epsilon=0} = -\frac{d}{d\epsilon}S(\rho(\epsilon))\bigg|_{\epsilon=0} - \mathrm{Tr}(\rho'(0)\log\sigma),$$

which is the stated identity. □

0.5.4. *Why this matters for emergent geometry.* The "redshift ansatz" (0.2) implicitly treats entanglement as modifying local clock rates. Corollary 0.6 makes that relationship operator-theoretic: small state variations change entropies and modular energies in lockstep. In the holographic literature, this is the algebraic root of the entanglement-equilibrium route to Einstein's equation; in our discrete setting it becomes a checkable matrix identity on reduced density operators extracted from the ribbon-graph state.

0.5.5. *Practical computation on graph patches.* Given a patch A with Hilbert space dimension $D = d^{|A|}$, computing $K_A = -\log\rho_A$ requires an eigendecomposition of a $D \times D$ matrix. For small $|A|$ (1–6 qudits) this is feasible; for larger patches one should instead work with: (i) moments $\mathrm{Tr}(\rho_A^n)$, (ii) Rényi entropies, or (iii) low-rank approximations obtained by tensor-network compression. From the present perspective the important point is that all these quantities are functions of the density operator, hence are stable under global phase and compatible with mixed/noisy states.

0.6. Einstein limit via entanglement equilibrium: what must be assumed. A conceptual route to Einstein equations from entanglement is the entanglement-equilibrium idea: for small causal diamonds, extremizing entanglement entropy at fixed volume yields Einstein's equation. We translate the logic into the present discrete setting and clearly mark what is assumption versus derivation.

0.6.1. *Assumptions.*

(1) **Local equilibrium:** on sufficiently small regions A (patches around vertices), the state is close to a reference state for which a first-law variation holds:

$$\delta S(A) = \delta\langle K_A\rangle.$$

(2) **Area term:** $S(A)$ has a leading "area" contribution proportional to boundary size (in a graph, number of cut edges) plus subleading terms.

(3) **Energy identification:** $\langle K_A\rangle$ acts like an energy functional for excitations in A.

These are strong assumptions; they are testable in a hardware testbed by checking first-law-like relations empirically on small subsystems.

0.6.2. *Discrete variational statement.* Let A be a local patch. Write

$$S(A) = \eta\,|\partial A| + S_{\mathrm{bulk}}(A),$$

with η setting units (bits per edge). Vary the state and (optionally) the graph weights. Under local equilibrium, $\delta S = \delta\langle K\rangle$ becomes:

$$\eta\,\delta|\partial A| + \delta S_{\mathrm{bulk}}(A) = \delta\langle K_A\rangle.$$

If δS_{bulk} is interpreted as "matter" and $\delta|\partial A|$ as "geometry", this is the discrete Einstein equation template.

Remark 0.7 (Why surface orders matter here). Surface orders constrain which local variations are allowed because local degrees of freedom are not arbitrary: they are local matrix orders glued by cocycles. Thus, the allowed variations of $|\partial A|$ and of K_A are coupled by algebraic constraints. In other words: the noncommutative local model replaces "free metric variation" by "allowed gluing-compatible variations".

0.7. A realistic numerical experiment: curvature from entanglement gradients on hyperbolic patches. Pick a hyperbolic tiling patch (§12.4) and embed it into hardware connectivity. Prepare two families of states:

- a baseline high-entanglement state (random circuit depth L),
- a gradient state where a subregion has reduced entanglement (shallower depth or partial measurement).

Compute:

(1) d_ψ from (0.1),
(2) curvature surrogates κ_ψ (angle defects or Ollivier–Ricci),
(3) local clock rates r_v as in Section 23.

Test two correlations:

$$\varepsilon_v \uparrow \Longrightarrow r_v \downarrow, \qquad \nabla\varepsilon \neq 0 \Longrightarrow \kappa_\psi \neq \text{const}.$$

The multiparameter persistence tool enters by tracking whether curvature and distance features persist across:

- threshold choices λ,
- noise realizations (bootstrap),
- coarse-graining levels (patch size).

0.8. Failure modes (and why they are informative). This is a high-risk modeling layer. Here are the failure modes that would be scientifically useful:

- **No stable metric:** d_ψ fluctuates wildly under small perturbations of W_ψ; persistence reveals intrinsic instability. This suggests the graph/state pair is not in a geometric paradigm.
- **No redshift correlation:** r_v is uncorrelated with ε_v after controlling for noise. This falsifies the simplest redshift ansatz (0.2).
- **Curvature surrogate mismatch:** κ_ψ does not track entanglement gradients. This suggests either wrong curvature notion or wrong metric extraction map f.
- **Holonomy decouples:** time holonomy invariants (Section 18) do not correlate with entanglement-induced geometry. This indicates the clock field is not correctly coupled to state-dependent data, and pushes attention back to the twisted-shift/valuation coupling.

A coherent theory must tell you *which* failure mode you should expect when assumptions are violated. That is exactly what the persistence framework is good at: it distinguishes stable phenomena from artifacts.

CHAPTER 21

Renormalization via graph quanvolution and graph quantum attention on ribbon graphs

This chapter adds a concrete, implementation-oriented bridge between the ribbon-graph/dessin formalism developed earlier in the paper and two practical families of learnable coarse-graining mechanisms that are now standard in machine learning: (i) convolution/pooling and (ii) attention. Our goal is *not* to import grids or sequences into the present context, but rather to express both mechanisms intrinsically on a fat-graph (a graph equipped with a cyclic ordering of half-edges at each vertex), and to do so for *cyclic qudits* of general period d, including the limiting "infinite-period" case.

A unifying theme is that the trainable primitives are (i) *multilinear* in their quantum inputs (unitaries and tensor contractions) and (ii) become *effectively nonlinear* once we allow measurements, classical post-processing (e.g. activations, normalizations), and/or conditioning. This is precisely the structure of renormalization: a local map that discards degrees of freedom while producing new effective variables at a coarser scale.

1. Cyclic qudits, finite or infinite period, and learnable coarse-graining channels

1.1. Cyclic qudits as group-algebra degrees of freedom. Fix a "period" parameter

$$d \in \mathbb{N}_{\geq 2} \cup \{\infty\}.$$

For finite d, the *cyclic qudit* is the Hilbert space $\mathcal{H}_d \cong \mathbb{C}^d$ with computational basis $\{|k\rangle : k \in \mathbb{Z}_d\}$. For $d = \infty$, a natural model is $\mathcal{H}_\infty \cong \ell^2(\mathbb{Z})$ with basis $\{|k\rangle : k \in \mathbb{Z}\}$ (angular momentum basis), and its Pontryagin dual "angle basis" $|\theta\rangle$ with $\theta \in [0, 2\pi)$, where $\langle k \mid \theta\rangle = \frac{1}{\sqrt{2\pi}} e^{ik\theta}$. Both cases can be packaged as the group algebra $\mathbb{C}[\mathbb{Z}_d]$, with the convention $\mathbb{Z}_\infty := \mathbb{Z}$.

The generalized (Weyl) shift and clock operators are

$$X_d|k\rangle = |k+1\rangle, \qquad Z_d|k\rangle = \omega^k|k\rangle, \qquad \omega = e^{2\pi i/d}$$

for finite d, with the usual relation $Z_d X_d = \omega X_d Z_d$. In the infinite-period case, one may view Z_∞ as multiplication by $e^{i\theta}$ in the θ-representation, and X_∞ as the unit shift on $\ell^2(\mathbb{Z})$; then $Z_\infty X_\infty = e^i X_\infty Z_\infty$ is interpreted in the exponentiated (Weyl) form. We will also use the qudit Fourier transform F_d defined by $F_d|k\rangle = \frac{1}{\sqrt{d}} \sum_{\ell \in \mathbb{Z}_d} \omega^{k\ell}|\ell\rangle$ (finite d), and its continuous analog $F_\infty : \ell^2(\mathbb{Z}) \leftrightarrow L^2(S^1)$.

1.2. Ribbon-graph locality and patch registers. Let $\Gamma = (V, E)$ be a ribbon graph (fat-graph) with a cyclic ordering of half-edges at each vertex. For a vertex $v \in V$, write $N(v)$ for its neighbors and $N_r(v)$ for the r-hop neighborhood (as an induced subgraph). The fat-graph structure gives a *cyclic order* on the incident half-edges at v, which we denote by

$$(e_1(v), e_2(v), \ldots, e_{\deg(v)}(v)).$$

When we form a "local patch register" for v, we will always order the corresponding qudits according to this cyclic order. This ensures that any weight-sharing or equivariance constraints we impose are compatible with the ribbon structure, not merely the underlying abstract graph.

1.3. Learned coarse-graining as a CPTP map. A single renormalization step is most cleanly expressed as a completely positive trace-preserving (CPTP) map. Fix a patch $S_v \subseteq V$ (e.g. $S_v = N_r(v)$ for a chosen r). Let ρ_{S_v} be the reduced density operator on the patch. A *learned coarse-graining channel* is a family of CPTP maps

$$\mathcal{R}_{\theta,v} : \mathcal{B}(\mathcal{H}_d^{\otimes|S_v|}) \to \mathcal{B}(\mathcal{H}_d^{\otimes m}),$$

parameterized by trainable parameters θ, and producing m "effective" qudits (or, more generally, m classical features obtained by measurement). A canonical form is

$$\mathcal{R}_{\theta,v}(\rho_{S_v}) \;=\; \mathrm{Tr}_{\mathrm{discard}}\Big[U_{\theta,v}\,\rho_{S_v}\,U_{\theta,v}^{\dagger}\Big], \tag{1.1}$$

where $U_{\theta,v}$ is a unitary acting on the patch, and discard denotes a chosen subset of degrees of freedom that are traced out (pooling). If we additionally measure part of the patch and feed the outcomes forward, (1.1) becomes a general quantum instrument; *nonlinearity* then arises at the level of the overall learning system via conditioning and classical post-processing.

Multilinearity versus effective nonlinearity. Unitary evolution is linear in ρ, but observables of the form

$$f(\rho;\theta) = \mathrm{Tr}\Big(O\,U_\theta \rho U_\theta^{\dagger}\Big)$$

are *multilinear* in the tensor factors of ρ when ρ is a product state across a patch, and are polynomial in the matrix elements of U_θ. Nonlinearities in practical architectures arise from: (i) pooling/partial trace (discarding factors), (ii) conditioning on measurement outcomes, and (iii) explicit classical nonlinearities applied to measured features (e.g. ReLU, sigmoid, softmax). This is the precise sense in which "learned multilinear maps with nonlinearities" naturally implement renormalization.

1.4. Finite-period truncations and quotients of the infinite-period model. The infinite-period model $\mathcal{H}_\infty \cong \ell^2(\mathbb{Z})$ is useful conceptually, but hardware and simulations require finite resources. Two standard reductions are:

(1) **Truncation (energy cutoff).** Fix $N \in \mathbb{N}$ and restrict to $\mathrm{span}\{|k\rangle : |k| \le N\}$, giving a $(2N+1)$-dimensional approximation. Truncation is appropriate when dynamics and states remain approximately band-limited in the $|k\rangle$ basis. A failure mode is "wrap-around" or leakage when gates create significant weight near the cutoff.

(2) **Quotient (periodization).** Impose the relation $k \sim k + d$, i.e. replace $\mathbb{Z}$ by $\mathbb{Z}_d$. Formally, this is passing from the group algebra $\mathbb{C}[\mathbb{Z}]$ to $\mathbb{C}[\mathbb{Z}_d]$. Quotients are appropriate when the model has an intrinsic periodicity (or when we deliberately enforce one as an inductive bias). A failure mode is aliasing: physically distinct modes become identified by the quotient.

In later examples we will keep the notation d and interpret $d = \infty$ as the conceptual limit, while implementations use one of the two finite reductions.

2. Quanvolutional renormalization on ribbon graphs (graph convolution)

Quanvolutional layers were introduced as a hybrid quantum–classical analog of convolution [7]: a small quantum circuit is applied repeatedly to local patches, and expectation values are used as features for a subsequent classical (or quantum) network. In the image setting, a patch is an $n \times n$ window; here the patch is an induced subgraph S_v around a vertex v.

A graph-native instantiation of the same philosophy—explicitly combining edge-local quantum "convolution" with measurement-based pooling—is the QGCN model of Zheng–Gao–Lü [10], which we adapt to ribbon graphs and cyclic qudits in Section 3.

2.1. Random versus trainable patch circuits (and why this looks like RG). In the original quanvolution proposal [7], the patch circuit is often taken to be *random* rather than trained: one samples a shallow circuit from a fixed gate set, applies it to each patch, and uses a small collection of expectation values as features. The classical network downstream then learns how to combine these features. Two points make this relevant to the present renormalization framing:

(1) **Random circuits as learned feature maps.** Even without training, a family of random local unitaries induces a rich, nonlinear feature map after measurement. In geometric terms, one is learning in the space of *pushforwards* of local patch measures through a family of multilinear maps.
(2) **Trainable circuits as adaptive coarse-graining.** When the patch circuit is trained, it becomes a bona fide *learned RG move*: it selects a local basis (via U_θ), compresses by discarding degrees of freedom, and exposes the effective observables (the readout) that are helpful for the task.

For ribbon graphs, both variants are natural. A random patch circuit provides a strong inductive bias while keeping training costs low; a trainable circuit offers greater expressivity at the expense of more quantum resources (shots) for gradient estimation.

2.2. From grid patches to ribbon-graph patches. Fix a patch rule $v \mapsto S_v$ (for example $S_v = N_r(v)$), and fix an ordering of the vertices in S_v consistent with the cyclic order of half-edges in the ribbon structure. For each patch we specify:

(1) an **encoding map** $x \mapsto \rho_{S_v}(x)$ from classical features (node/edge labels) into a product (or weakly entangled) state on the patch register;
(2) a **patch circuit** U_θ, shared across all v (weight sharing);
(3) a **readout** given by a family of observables $\{O_a\}_{a=1}^{p}$ on a subset of the patch qudits.

The quanvolutional feature at v is then

$$\phi_a(v) \;=\; \mathrm{Tr}\Big(O_a\, U_\theta\, \rho_{S_v}(x)\, U_\theta^\dagger\Big), \qquad a = 1, \dots, p. \tag{2.1}$$

In practice the trace is estimated by sampling. Equation (2.1) is exactly a local renormalization step: a patch is mapped to a smaller feature vector (or to a smaller quantum register if we keep the post-unitary reduced state on a subset of qudits).

2.3. A ribbon-compatible graph convolution ansatz. Let v have degree $\deg(v) = q$ and incident half-edges ordered cyclically. A simple and ribbon-compatible patch circuit on the star $S_v = \{v\} \cup N(v)$ is

$$U_\theta^{(v)} \;=\; \Big(\prod_{j=1}^{q} \mathrm{CZ}_d^{(v,u_j)}\Big)\Big(\prod_{j=1}^{q} R_d^{(u_j)}(\alpha_j)\Big)\, R_d^{(v)}(\beta)\, F_d^{(v)}, \tag{2.2}$$

where $(u_1, \dots, u_q)$ are the neighbors of v in cyclic order, $R_d(\cdot)$ denotes a chosen one-qudit rotation family generated by X_d and Z_d, and

$$\mathrm{CZ}_d \;:=\; \sum_{a,b\in\mathbb{Z}_d} \omega^{ab}\, |a,b\rangle\langle a,b|$$

is the generalized controlled-phase. For $d = \infty$, replace CZ_d by the corresponding Weyl-type entangling gate $e^{i\,\hat{n}\otimes\hat{n}}$ on the momentum basis (or its truncated/periodized version).

The readout can be taken as generalized Pauli expectations on the central site, e.g.

$$\phi_1(v) = \langle Z_d^{(v)}\rangle, \qquad \phi_2(v) = \langle X_d^{(v)}\rangle,$$

or, more invariantly, a small set of Fourier modes $\langle (Z_d^{(v)})^m\rangle$.

2.4. Pooling as edge contraction: a QCNN/MERA-style renormalization step. To build a *hierarchical* renormalization (rather than a single feature extraction layer), we need pooling that produces a coarser ribbon graph. One convenient pooling rule on a graph is: choose a maximal matching $M \subseteq E$ (disjoint edges), and for each matched edge $(u, v) \in M$, apply a two-vertex channel that produces a single effective vertex, i.e. contract (u, v). At the level of Hilbert spaces, a pooling isometry is a map

$$W : \mathcal{H}_d^{\otimes 2} \to \mathcal{H}_d,$$

implemented as a unitary on $\mathcal{H}_d^{\otimes 2}$ followed by discarding one factor. On a matched edge we may take, for example,

$$W(\rho_{uv}) = \mathrm{Tr}_v \left[U_\theta^{(uv)} \, \rho_{uv} \, (U_\theta^{(uv)})^\dagger \right],$$

where $U_\theta^{(uv)}$ is built from generalized SUM and phase gates,

$$\mathrm{SUM}_d : |a, b\rangle \mapsto |a, a + b \pmod d\rangle.$$

When Γ is a ribbon graph, contracting an edge has a canonical effect on the cyclic order data at the endpoints; thus the pooled graph remains a ribbon graph. Iterating this matching-and-contraction procedure yields a bona fide renormalization flow $\Gamma \to \Gamma_1 \to \Gamma_2 \to \cdots$.

2.5. A worked micro-example: trivalent dessin patch. Consider a trivalent ribbon graph (typical for dessins) and take the star patch $S_v = \{v\} \cup N(v)$. Encode real node features $x_u \in \mathbb{R}$ into one-qudit phase states by $|\psi(x_u)\rangle = Z_d^{\lfloor \kappa x_u \rfloor}|0\rangle$ for a scale κ (finite d), or $|\psi(x_u)\rangle = e^{i x_u \hat{n}}|0\rangle$ in the $d = \infty$ model (followed by truncation). Apply the star circuit (2.2) and read out $\phi_1(v) = \langle Z_d^{(v)} \rangle$. Even this minimal construction produces a nonlinear function of the neighborhood features once we post-process $\phi_1(v)$ (e.g. apply a classical nonlinearity and/or stack layers), while keeping the inductive bias that the computation is ribbon-local.

3. Renormalization via quantum graph convolutional neural networks (QGCN) on ribbon graphs

The quanvolutional discussion above deliberately started from the most "physics" viewpoint: a local quantum circuit on a patch, followed by readout and (optionally) pooling, is already a renormalization step. The *Quantum Graph Convolutional Neural Network* (QGCN) architecture of Zheng–Gao–Lü [10] is a clean reference point because it makes explicit how graph convolution, pooling, and measurement can be implemented by parameterized quantum circuits, while keeping the overall layout close to the classical GCN paradigm.

Our aim in this section is threefold:

(1) to extract the *renormalization-theoretic core* of QGCN, namely "local aggregation + dimensional reduction",
(2) to recast the construction *intrinsically on a ribbon graph* (no grids, no sequences, no loss of cyclic-order data),
(3) to generalize from *qubits* to *cyclic qudits of period* $d \in \mathbb{N} \cup \{\infty\}$, and to make the finite-period truncation/quotient issues completely explicit.

3.1. Learned multilinear patch maps and where nonlinearity really enters. A recurring point in this chapter is that "quantum layers are multilinear" and yet "the overall architecture is nonlinear". Here is the clean statement in the present graph setting.

Fix a patch S_v and an encoding map $x \mapsto \rho_{S_v}(x)$. For a family of observables $\{O_a\}_{a=1}^p$ and a patch unitary U_θ, the measurable features are

$$\phi_a(v; x, \theta) \;:=\; \mathrm{Tr}\Big(O_a \, U_\theta \, \rho_{S_v}(x) \, U_\theta^\dagger \Big). \tag{3.1}$$

If $\rho_{S_v}(x)$ is a tensor product of *single-site amplitude encodings*, $\rho_{S_v}(x) = \bigotimes_{u\in S_v} |\psi(x_u)\rangle\langle\psi(x_u)|$ with $|\psi(x_u)\rangle = \sum_i x_{u,i}|i\rangle$, then each ϕ_a is a *multilinear polynomial* in the amplitudes and their conjugates:

$$\phi_a(v;x,\theta) = \sum_{Gri,Grj} C^{(a)}_{Gri,Grj}(\theta) \prod_{u\in S_v} x_{u,i_u}\,\overline{x_{u,j_u}}, \tag{3.2}$$

where $Gri = (i_u)_{u\in S_v}$ and $Grj = (j_u)_{u\in S_v}$ index basis labels on the patch. Equivalently, for a single register $|\psi(x)\rangle$ of dimension D, $\phi_a(x,\theta) = x^* M_a(\theta) x$ is a quadratic form with $M_a(\theta) = U_\theta^\dagger O_a U_\theta$.

Thus, *the quantum part is algebraically tame*: it is a learned multilinear (tensor) map. The true nonlinearities arise from operations that are *essentially renormalization*:

- **Pooling / partial trace:** discarding qudits is not invertible and changes the effective degrees of freedom.
- **Measurement and conditioning:** measurement outcomes select branches of an instrument (nonlinear at the level of the induced update rule on classical features).
- **Classical nonlinearities:** activations, normalizations, and softmax applied to measured features.

This division of labor is exactly what one expects from RG: linear/multilinear local physics together with nonlinear state reduction and rescaling steps.

3.2. The QGCN architecture of Zheng–Gao–Lü as a ribbon-local RG move. Zheng–Gao–Lü [10] propose a four-block architecture: *(i) quantum state preparation*, *(ii) quantum graph convolutional layers*, *(iii) quantum pooling layers*, and *(iv) quantum measurement*. We recall each block in some detail before adapting the whole to ribbon graphs with cyclic qudits.

Block (i): quantum state preparation (amplitude encoding). Given a graph $G = (V, E)$ with $|V| = N$ vertices and a feature matrix $X \in \mathbb{R}^{N\times d_{\text{in}}}$, QGCN encodes graph data into a quantum state via *amplitude encoding*:

$$|\psi_X\rangle = \frac{1}{\|X\|_F} \sum_{i=0}^{N-1} \sum_{j=0}^{d_{\text{in}}-1} X_{ij}\,|i\rangle|j\rangle,$$

using $\lceil \log_2 N\rceil + \lceil \log_2 d_{\text{in}}\rceil$ qubits. The adjacency structure is encoded separately in "topology qubits" that control whether a two-qubit gate is applied on a given pair [10].

Block (ii): quantum graph convolution layers. A convolution layer applies a universal two-qubit gate $U^{(2)} \in \mathrm{SU}(4)$ on each pair of connected vertices. In [10], $U^{(2)}$ is decomposed into 3 CNOT gates and 15 basic single-qubit rotation gates (the Khaneja–Glaser decomposition), yielding a constant-depth parameterized circuit per edge. The "graph convolution" interpretation is that each application of $U^{(2)}$ on edge (u, v) mixes the quantum features of u and v—the quantum analog of message passing. Stacking L such layers propagates information L hops.

Block (iii): quantum pooling. After convolution, a subset of qubits is measured in the computational basis, producing classical bits. Conditioned on these measurement outcomes, a unitary correction is applied to the remaining (unmeasured) qubits. This implements a quantum instrument whose classical branch determines the nonlinear update rule for the coarse features—the renormalization step.

Block (iv): quantum measurement (readout). The final block measures all remaining qubits to produce a classical feature vector used for downstream classification or regression. In [10], the measurement is in the Pauli-Z basis, and the resulting expectation values are the features.

For our purposes, the key conceptual step is to *externalize the adjacency*:

> *on a physical graph device, adjacency is not an input register but the native connectivity graph on which two-site gates exist.*

Thus the "controlled-by-topology" mechanism becomes simply "apply a fixed two-site gate on each physical edge". This is exactly the graph-centric viewpoint compatible with dessins/fat-graphs.

Concretely, let $\Gamma = (V, E)$ be the ribbon graph of the computation. A QGCN-style *convolution layer* is specified by a two-site unitary $U_\theta^{(2)}$ (shared across edges) and a schedule (e.g. edge coloring) so that gates on disjoint edges can be executed in parallel. One layer applies $U_\theta^{(2)}$ to every edge:

$$\rho \longmapsto \Big(\prod_{(u,v)\in E}^{\text{schedule}} U_\theta^{(2)}(u,v)\Big)\,\rho\,\Big(\prod_{(u,v)\in E}^{\text{schedule}} U_\theta^{(2)}(u,v)\Big)^\dagger. \tag{3.3}$$

As in [10], stacking L such layers implements higher-order neighborhood aggregation (because information propagates L hops in L rounds of edge-local mixing).

A QGCN-style *pooling layer* then reduces the active degrees of freedom. The pooling circuit in [10] measures a subset of qubits and conditionally applies a unitary on remaining qubits based on the measurement outcomes. In renormalization language, this is a local quantum instrument whose classical outcomes drive a nonlinear update rule for coarse features.

On a ribbon graph, the most geometrically transparent pooling rule is still *edge contraction along a matching* (Section 2): choose a maximal matching $M \subseteq E$, and on each $(u, v) \in M$ apply an isometry $W : \mathcal{H}_d^{\otimes 2} \to \mathcal{H}_d$ implemented by "unitary + discard" (and optionally measurement-conditioned corrections). Because contraction is canonical in the ribbon category, the cyclic order data is preserved and the pooled graph remains a ribbon graph.

3.3. Generalization from qubits to cyclic qudits of period d. The original QGCN paper [10] is written in the qubit language (amplitude encoding into 2^n-dimensional states, two-qubit unitaries in SU(4), and Pauli-Z measurements). In our setting each site carries a cyclic qudit $\mathcal{H}_d$ with $d \in \mathbb{N} \cup \{\infty\}$ (Section 1). The replacements are systematic:

(1) **Local feature encoding.** Amplitude encoding becomes the map

$$x \in \mathbb{C}^{d^n},\ \|x\|_2 = 1 \quad \longmapsto \quad |\psi_d(x)\rangle = \sum_{i=0}^{d^n-1} x_i |i\rangle \ \in (\mathcal{H}_d)^{\otimes n}.$$

For $d = \infty$, one uses a truncation to a finite-dimensional subspace or a quotient to $\mathbb{Z}_d$ (Section 1).

(2) **Two-site "convolution" gates.** Two-qubit universality statements used in [10] (e.g. decompositions into CNOTs and one-qubit rotations) generalize to two-qudit universality: a generic two-qudit unitary in $\mathrm{SU}(d^2)$ can be synthesized from one-qudit $\mathrm{SU}(d)$ rotations together with an entangling gate such as SUM_d or CZ_d. For cyclic qudits, SUM_d is the natural analog of CNOT,

$$\mathrm{SUM}_d : |a, b\rangle \mapsto |a, a + b \pmod d\rangle.$$

In the $d = \infty$ (rotor) picture, replace modular addition by addition on $\mathbb{Z}$, and implement it approximately on a truncated subspace.

(3) **Readout.** Pauli-Z expectation values become Weyl-mode expectations such as $\langle (Z_d)^m \rangle$ for small m, or, in the rotor model, $\langle e^{im\theta} \rangle$. This is particularly aligned with the "clock" interpretation of cyclic qudits: we are literally reading out low Fourier modes of an angular distribution.

The practical message is that QGCN is not "a qubit model" but a *group-algebra model*: once the cyclic group $\mathbb{Z}_d$ is the organizing principle, the qubit case is simply $d = 2$.

3.4. Pooling as a measurement-conditioned contraction channel. To emphasize the RG reading, it is helpful to write pooling as a channel. Fix an edge $(u, v) \in M$ in a matching. A pooling layer specifies a channel

$$\mathcal{P}_\theta^{(uv)} : \mathcal{B}(\mathcal{H}_d^{\otimes 2}) \to \mathcal{B}(\mathcal{H}_d), \qquad \mathcal{P}_\theta^{(uv)}(\rho_{uv}) \ = \ \sum_m \mathrm{Tr}_v\Big[V_{\theta,m}\, U_\theta\, \rho_{uv}\, U_\theta^\dagger\, V_{\theta,m}^\dagger\Big], \tag{3.4}$$

where U_θ is a two-site unitary, $\{V_{\theta,m}\}$ are (possibly trivial) conditional corrections depending on a measurement outcome m obtained from measuring v, and the trace discards the measured/pooled site. Equation (3.4) is the natural graph generalization of the pooling block in [10].

Iterating "edge-layer + pooling" defines a discrete RG flow on ribbon graphs:

$$(\Gamma, \rho) \longmapsto (\Gamma_1, \rho_1) \longmapsto (\Gamma_2, \rho_2) \longmapsto \cdots,$$

where Γ_{k+1} is obtained from Γ_k by contracting a matching and inheriting the ribbon structure. In this form it becomes completely transparent how to attach persistence-based diagnostics (Section 6): one can track which topological/geometric features of the state-induced filtrations persist across RG scale.

3.5. A worked micro-example: a 3-vertex path and one QGCN-RG step. Consider the path graph u–v–w with the induced ribbon structure (trivial cyclic order at each degree-2 vertex). Let each site carry a cyclic qudit $\mathcal{H}_d$. Encode scalar features $x_u, x_v, x_w \in \mathbb{R}$ into phase states $|\psi(x)\rangle := Z_d^{\lfloor \kappa x \rfloor}|0\rangle$ (finite d) or $|\psi(x)\rangle := e^{ix\hat{n}}|0\rangle$ (rotor model), and begin with the product state $\rho_0 = |\psi(x_u)\rangle\langle\psi(x_u)| \otimes |\psi(x_v)\rangle\langle\psi(x_v)| \otimes |\psi(x_w)\rangle\langle\psi(x_w)|$.

Convolution step. Apply a shared two-site entangler $U_\theta^{(2)}$ on (u, v) and (v, w) (in two rounds if needed to avoid overlap). For instance, a minimal cyclic-qudit message-passing gate on an edge is (6.1). This produces ρ_1.

Pooling (contraction) step. Measure the middle qudit v in the computational basis, obtaining outcome $m \in \mathbb{Z}_d$. Conditioned on m, apply a correction $V_{\theta,m}$ (often a simple X_d-shift or phase) to u or w, and then discard v. The result is an effective two-site state ρ_{uw} on the contracted graph u–w.

Even in this toy example one sees the RG structure: the edge-local unitary is multilinear, while the measurement-conditioned pooling creates a nonlinear effective update rule for the coarse variables (e.g. the measured Fourier modes at u and w). On a hyperbolic ribbon graph with $\sim 10^5$ sites (Section 6), the same local primitives execute in a small number of rounds because the degree is bounded and the edge chromatic number is small.

3.6. Relation to geodesic CNN on surfaces: from continuous patches to ribbon-graph qudits. Masci–Boscaini–Bronstein–Vandergheynst [11] introduced *geodesic convolutional neural networks* (GCNN) on manifolds by replacing the Euclidean translation used in classical CNNs with local geodesic polar coordinates. In this subsection we recall their construction in some detail, describe the layer taxonomy of GCNN, and explain how the quanvolutional framework on ribbon graphs developed above is a natural combinatorial and quantum-hardware-ready counterpart.

3.6.1. *Geodesic convolution on a manifold.* Let X be a smooth Riemannian manifold (or a triangulated surface). For each point $x \in X$, the *local geodesic polar coordinate system* $\Omega(x)\colon B_{\rho_0}(x) \to [0, \rho_0] \times [0, 2\pi)$ maps the geodesic ball of radius ρ_0 into radial and angular coordinates (ρ, θ). A signal $f\colon X \to \mathbb{R}^P$ is *interpolated into the patch* by the **patch operator**

$$\big(D(x)f\big)(\rho, \theta) \;=\; \int_X v_{\rho,\theta}(x, x')\, f(x')\, dx', \tag{3.5}$$

where the interpolation weights $v_{\rho,\theta}$ are products of a radial Gaussian $v_\rho(x, x') \propto e^{-(d_X(x,x')-\rho)^2/\sigma_\rho^2}$ and an angular Gaussian $v_\theta(x, x') \propto e^{-d_X^2(\Gamma(x,\theta),x')/\sigma_\theta^2}$, with $\Gamma(x, \theta)$ the geodesic ray from x in direction θ.

Because the choice of angular origin is arbitrary, the **geodesic convolution** (GC) of the patch with a filter $a(\theta, r)$ is defined with a shift $\Delta\theta$:

$$(f \star a)(x) \;=\; \sum_{\theta, r} a(\theta + \Delta\theta,\, r)\, \big(D(x)f\big)(r, \theta), \tag{3.6}$$

and the convolution is evaluated at *all* N_θ rotations $\Delta\theta = 0, \frac{2\pi}{N_\theta}, \dots, \frac{2\pi(N_\theta-1)}{N_\theta}$, producing N_θ outputs per filter. For a bank of P input channels and Q output filters, each rotated by N_θ angles, the GC layer output is

$$f^{\text{out}}_{\Delta\theta,q}(x) \;=\; \sum_{p=1}^{P} (f_p \star a_{\Delta\theta,qp})(x), \qquad q = 1, \dots, Q. \tag{3.7}$$

3.6.2. *Layer taxonomy of GCNN.* The GCNN architecture of [11] composes layers from the following palette:

(1) **Linear (LIN) layer.** A pointwise linear combination of input channels, optionally followed by a nonlinearity ξ (e.g. ReLU):

$$f^{\text{out}}_q(x) = \xi\Big(\sum_{p=1}^{P} w_{qp}\, f^{\text{in}}_p(x)\Big), \qquad q = 1, \dots, Q.$$

This adjusts input/output dimensions without altering the geometry.

(2) **Geodesic Convolution (GC) layer.** As in (3.7), applying all N_θ rotations of the filter bank. This is the core layer that replaces Euclidean convolution.

(3) **Angular Max-Pooling (AMP) layer.** Eliminates the angular coordinate ambiguity by taking the maximum over all rotations:

$$f^{\text{out}}_p(x) = \max_{\Delta\theta}\; f^{\text{in}}_{\Delta\theta,p}(x), \qquad p = 1, \dots, P.$$

After this layer the output is rotation-invariant with respect to the angular origin.

(4) **Fourier Transform Magnitude (FTM) layer.** An alternative to AMP that first applies the patch operator (at each (ρ, θ) per input dimension), takes the Fourier transform in the angular coordinate, and returns the absolute value:

$$f^{\text{out}}_p(\rho, \omega) = \Big|\sum_{\theta} e^{-i\omega\theta}\, (D(x) f^{\text{in}}_p)(x)(\rho, \theta)\Big|,$$

yielding complex-phase-invariant features.

(5) **Covariance (COV) layer.** Aggregates point-wise descriptors into a global shape descriptor $Grf^{\text{out}} = \int_X (Grf^{\text{in}}(x) - \boldsymbol{\mu})(Grf^{\text{in}}(x) - \boldsymbol{\mu})^\top\, dx$, used for tasks like shape retrieval.

A key insight of [11] is that several classical spectral descriptors are *special cases* of GCNN:

- *Heat kernel signature (HKS)* is a fixed LIN layer with band-pass filters $\tau_\nu(\lambda) = \exp(-t\lambda)$.
- *Wave kernel signature (WKS)* uses filters $\tau_\nu(\lambda) = \exp\big(\frac{\log \nu - \log \lambda}{2\sigma^2}\big)$.
- *Optimal spectral descriptors (OSD)* are obtained by a *learnable* LIN layer parametrized via B-splines $\tau_q(\lambda) = \sum_m a_{qm}\beta_m(\lambda)$.
- *Intrinsic shape context* is a fixed LIN layer producing HKS/WKS descriptors followed by a fixed FTM layer.

3.6.3. *From geodesic patches to ribbon-graph cyclic ordering: a combinatorial bridge.* A ribbon graph Γ embedded in a surface Σ provides a *combinatorial discretization* of the geodesic patch construction. The formal correspondence is:

GCNN on a manifold	$\longleftrightarrow$	**Quanvolution on a ribbon graph**
Point $x \in X$	$\longleftrightarrow$	Vertex $v \in V(\Gamma)$
Geodesic ball $B_{\rho_0}(x)$	$\longleftrightarrow$	r-neighborhood $N_r(v)$
Angular coordinate $\theta \in [0, 2\pi)$	$\longleftrightarrow$	Cyclic order σ_v at vertex v
N_θ angular bins	$\longleftrightarrow$	$\deg(v)$ cyclic positions
Radial bins (N_ρ levels)	$\longleftrightarrow$	Graph distance shells $\{d(v, u) = k\}$
Patch operator $D(x)$	$\longleftrightarrow$	Feature encoding $\lvert\psi(h_u)\rangle$ for $u \in N_r(v)$
Learned filter $a(\theta + \Delta\theta, r)$	$\longleftrightarrow$	Parameterized gate $U_\theta^{(2)}$ on edge (v, u)
Angular rotation by $\Delta\theta$	$\longleftrightarrow$	Cyclic shift of half-edge labels at v
AMP ($\max_{\Delta\theta}$)	$\longleftrightarrow$	Max over cyclic shifts; or X_d-shift gate
FTM ($\lvert\hat{f}(\omega)\rvert$)	$\longleftrightarrow$	F_d-basis measurement, discard phase
ReLU / activation ξ	$\longleftrightarrow$	Measurement + classical post-processing

Proposition 3.1 (GCNN as a classical shadow of quanvolution on ribbon graphs). *Let Γ be a ribbon graph embedded in a surface Σ, with $d := \max_v \deg(v)$. Equip each vertex v with a cyclic qudit $\mathcal{H}_d$ (period d matching the maximal degree). Define the* discrete angular coordinate *at a vertex v of degree δ_v as $\theta_v^{(j)} := 2\pi j/\delta_v$ for $j \in \mathbb{Z}_{\delta_v}$, indexed by the cyclic ordering of half-edges at v. Then:*

(1) The GC layer (3.7) *on Σ, restricted to* 1*-neighborhoods and discretized at the vertices and cyclic positions of Γ, reduces to a message-passing update of the form* (3.2) *with the parameterized gate applied to each edge (v, u) depending on the cyclic position of the half-edge $v \to u$.*

(2) The AMP layer corresponds to taking the maximum over cyclic-shift orbits of the gate outcomes; in the quantum setting, one instead applies X_d^j to the state at v before the gate and takes the maximum post-measurement, which is the cyclic-qudit analog of pooling over angular rotations.

(3) The FTM layer corresponds to measuring the qudit at v in the Fourier (F_d) basis and discarding the phase, yielding an output that depends on the absolute value of each Fourier component—precisely $\lvert\langle(Z_d)^m\rangle\rvert$.

In this sense, the QGCN-style quanvolution on ribbon graphs (Section 3.2) is a quantum-hardware-native generalization of geodesic convolution on surfaces, with cyclic qudits providing a natural home for angular and Fourier-mode features.

Remark 3.2 (Infinite period and continuous geodesic limit). In the $d = \infty$ rotor model ($\mathcal{H}_\infty \cong L^2(S^1)$), the cyclic qudit at each vertex becomes a genuine angular degree of freedom on the circle, and the Fourier modes $(Z_\infty)^m = e^{im\theta}$ form a countable orthonormal family. The discrete-to-continuous bridge of Proposition 3.1 then becomes exact in the limit $N_\theta \to \infty$, $N_\rho \to \infty$: the GCNN patch operator (3.5) converges to the patch integral, and the GC filter bank (3.7) converges to a learned filter on $L^2(S^1 \times [0, \rho_0])$. In practice, truncation to a $(2N + 1)$-dimensional subspace (Section 6) or quotienting to $\mathbb{Z}_d$ provides a finite working approximation with resolution controlled by the cutoff.

Remark 3.3 (QGAT parameter efficiency). From a practical standpoint, the parameter overhead of the quantum approach is moderate. For instance, [12] reports that a 4-head QGAT with 8 qubits and 6 strongly-entangling layers uses approximately 6.72×10^6 parameters on the PPI benchmark, compared to 6.44×10^6 for GAT and 12.84×10^6 for GATv2, while achieving comparable F1 scores. The cyclic-qudit generalization does not change the parameter count substantially (the variational circuit has the same number of real parameters per gate, independent of d), although training-time overhead from quantum simulation is significant (5–6×

slower than classical baselines when using PennyLane-based simulators [12]). On native hardware, this overhead vanishes and the per-shot execution time is determined by circuit depth, not d.

4. Renormalization via graph quantum attention (graph attention)

Attention differs from convolution in that the neighborhood aggregation weights are *data-dependent*. This makes attention particularly natural for the present setting because dessins/fat-graphs already encode a rich combinatorial structure; attention allows the model to learn which parts of that structure are relevant for a given task.

4.1. Graph attention as adaptive message passing. Let $h_v^{(\ell)}$ be a feature at vertex v at layer ℓ (classical or quantum). A graph-attention update has the schematic form

$$h_v^{(\ell+1)} = \sigma\left(\sum_{u\in N(v)\cup\{v\}} \alpha_{vu}^{(\ell)}\, \mathsf{V}_\theta\left(h_u^{(\ell)}\right)\right), \qquad \alpha_{vu}^{(\ell)} \propto \exp\left(\langle \mathsf{Q}_\theta(h_v^{(\ell)}), \mathsf{K}_\theta(h_u^{(\ell)})\rangle\right), \tag{4.1}$$

with trainable maps $\mathsf{Q}, \mathsf{K}, \mathsf{V}$ and a normalization over $u \in N(v) \cup \{v\}$. The nonlinearity arises from the normalization (softmax) and the activation σ.

4.2. Quantum attention primitives and Gaussian-projected self-attention. One practical route to quantum attention is to realize the "query/key/value" maps as parameterized quantum circuits and estimate the required inner products by quantum overlap tests. Another route, emphasized in the quantum-attention paper [8], is for a fully graph-native attention mechanism in which a single variational circuit produces many attention heads in parallel (rather than approximating the attention kernel), see the QGAT architecture [12], adapted to cyclic qudits and ribbon graphs in Section 5.

Gaussian-projected approximation to the attention kernel. At a high level, one rewrites the softmax kernel in a feature-map form and approximates it by a Gaussian random projection, which yields attention weights computable from a manageable number of random features and trainable circuits.

A concrete Gaussian-projected scoring rule. In [8], one particularly simple (and hardware-friendly) attention score is obtained by measuring a single Pauli observable on the query and key outputs and exponentiating the squared difference. In their notation, for token s attending to token j,

$$\alpha_{s,j} := \exp\left(-\left(\langle Z_q\rangle_s - \langle Z_k\rangle_j\right)^2\right), \tag{4.2}$$

$$= \exp\left(-\left(\langle s|Z_q|s^*\rangle - \langle j|Z_k|j^*\rangle\right)^2\right) \tag{4.3}$$

followed by normalization. This replaces the usual dot-product score by a Gaussian kernel on a *measured* one-dimensional projection, which can drastically reduce quantum resources.

For cyclic qudits, there is an evident generalization: replace Z by a chosen Fourier mode of the clock operator, e.g. use $\mathrm{Re}\,\langle (Z_d)^m\rangle$ or $\mathrm{Im}\,\langle (Z_d)^m\rangle$ for some small m, and set

$$\alpha_{v,u} := \exp\left(-\left(\mathrm{Re}\,\langle (Z_d)^m\rangle_{q_v} - \mathrm{Re}\,\langle (Z_d)^m\rangle_{k_u}\right)^2\right),$$

with normalization over $u \in N_r(v)$. In the $d = \infty$ model (quantum rotor), $(Z_\infty)^m$ is multiplication by $e^{im\theta}$ in the angle basis, so this score compares low Fourier modes of the learned angular distributions. The key operational point is that *only local, single-site measurements are needed to score edges*, making this style of attention compatible with strict locality and limited readout bandwidth.

For ribbon graphs, we restrict attention to local neighborhoods $N_r(v)$ (or to edges) so that the computation remains compatible with the local gate constraints of hardware. The resulting *graph quantum attention layer* is:

(1) **Local query/key/value circuits.** For each vertex v, prepare quantum registers $|q_v\rangle, |k_v\rangle, |v_v\rangle$ by applying parameterized circuits $U_Q(\theta_Q), U_K(\theta_K), U_V(\theta_V)$ to an encoded state $|\psi(h_v)\rangle$. For cyclic qudits these circuits can be built from X_d, Z_d, F_d and two-site Weyl entanglers.

(2) **Edge-local similarity estimation.** For each edge (v, u) (or $u \in N_r(v)$), estimate a similarity score s_{vu}, e.g. via a generalized SWAP/Hadamard test giving an estimate of $|\langle q_v \mid k_u\rangle|^2$, or via a random-feature (Gaussian-projected) approximation.

(3) **Classical normalization.** Compute $\alpha_{vu} = \exp(s_{vu})/\sum_{w\in N_r(v)} \exp(s_{vw})$.

(4) **Aggregation/pooling.** Update an effective feature/state at v by a weighted mixture of value registers, and optionally pool to a coarser graph by contracting edges with large α_{vu}.

Renormalization interpretation. Attention defines a *data-dependent* coarse-graining: rather than averaging uniformly over a patch, it learns which edges/vertices to keep and which to suppress. In a ribbon-graph setting this can be sharpened by enforcing that α_{vu} respects the cyclic order around v (e.g. by restricting the scoring circuit to depend on relative cyclic position), so that the learned renormalization does not destroy the fat-graph structure.

4.3. A worked micro-example: attention on a heptagonal face. Suppose Γ contains a heptagonal face (as in common hyperbolic tilings). Let v be a vertex on that face and take $N_1(v)$ as the neighborhood. Choose a single-head attention layer in which the similarity score on an adjacent vertex u is estimated by the overlap

$$s_{vu} \approx \log\Big(|\langle q_v \mid k_u\rangle|^2 + \varepsilon\Big),$$

with a small stabilizer $\varepsilon > 0$ for numerical stability. A concrete cyclic-qudit circuit for preparing q_v from a feature $h_v \in \mathbb{R}$ is

$$|q_v\rangle = F_d\, Z_d^{\lfloor \kappa h_v \rfloor}\, F_d^\dagger |0\rangle,$$

which maps h_v into a localized "momentum" wavepacket (finite d) or its truncated analog ($d = \infty$). Similar choices apply for k_u. The overlap test is then a short, edge-local circuit. Because hyperbolic graphs have small diameter (growing only logarithmically with $|V|$ for fixed degree), a small number of attention layers already yields long-range sensitivity, which is exactly the kind of "RG compression" one exploits on negatively curved geometries.

5. Renormalization via quantum graph attention networks (QGAT) on ribbon graphs

The Gaussian-projected attention discussion above emphasized a hardware-friendly point: *one can often score edges using only local, low-bandwidth measurements*. The recently proposed *Quantum Graph Attention Network* (QGAT) of Ning–Li–Chen [12] pushes in a complementary direction: it uses a variational quantum circuit to generate *multi-head attention logits* directly from amplitude-encoded edge features, exploiting quantum parallelism to share parameters across heads.

In this section we transplant the QGAT mechanism into the present dessin/fat-graph setting, with two modifications: (i) we treat the underlying structure as a *ribbon graph* (so cyclic order is part of the data), and (ii) we generalize from qubits to cyclic qudits of finite or infinite period.

5.1. QGAT recap: a single circuit producing many attention heads. QGAT [12] starts from node features $h \in \mathbb{R}^{N\times d_{\text{in}}}$ and an edge list E. After a classical linear projection W into a multi-head space, QGAT

forms for each edge (i, j) a concatenated vector a_{ij} built from projected and raw node features, and compresses it to the input length required by amplitude encoding. In the notation of [12], one arrives at a vector $a'_{ij} \in \mathbb{R}^{2^{n_q} \cdot \lceil h/n_q \rceil}$ that is amplitude-encoded into n_q qubits:

$$|\psi(a'_{ij})\rangle = \sum_{t=0}^{2^{n_q}-1} (a'_{ij})_t \, |t\rangle.$$

A strongly-entangling variational circuit $U(\theta)$ is applied, and *each qubit* is measured in Z to produce one logit:

$$e_{ij}^{(k)} := \langle \psi(a'_{ij}) \mid U(\theta)^\dagger Z_k U(\theta) \mid \psi(a'_{ij}) \rangle, \qquad k = 1, \ldots, n_q. \tag{5.1}$$

These logits are normalized by softmax over neighbors to obtain attention weights $\alpha_{ij}^{(k)}$, and node updates are formed by the usual attention aggregation (concat or mean) [12]. A key point stressed in [12] is that the same circuit evaluation yields *many heads at once* by reading out different qubits, providing parameter sharing and potential efficiency advantages.

5.2. Ribbon-graph adaptation: encoding cyclic order and respecting locality. On a ribbon graph, each vertex i comes with a cyclic order of incident half-edges. This structure is absent in ordinary graphs but is central for dessins and for surface-embedded computation. There are (at least) two principled ways to incorporate it into attention:

(A) Cyclic position as an explicit feature. For an oriented edge $i \to j$, define

$$p(i \to j) \in \mathbb{Z}_{\deg(i)}$$

to be the index of the half-edge $(i \to j)$ in the cyclic ordering at i. This is a *cyclic variable* and can be encoded naturally into a cyclic qudit or into a phase feature (Fourier mode). One can then enlarge the edge feature vector by including $p(i \to j)$ and (optionally) a small set of its Fourier features $\big(\cos(2\pi m p/\deg(i)), \sin(2\pi m p/\deg(i))\big)$. This ensures the learned attention coefficients can depend on the ribbon structure.

(B) Cyclic equivariance by architectural constraint. Alternatively, one can enforce that the scoring circuit depends only on *relative cyclic offsets* and share parameters across rotations around i, mirroring how classical CNNs share parameters across translations. This produces a ribbon-equivariant attention mechanism: rotating the half-edge order rotates intermediate activations but leaves invariants (e.g. pooled features) unchanged.

Both choices are compatible with strict locality: for a radius-r neighborhood $N_r(i)$, attention weights are computed only for edges (i, j) with $j \in N_r(i)$.

5.3. Cyclic-qudit generalization of QGAT: Weyl measurements and qudit entangling layers. To generalize (5.1) from qubits ($d = 2$) to cyclic qudits ($d \geq 2$ or $d = \infty$), we replace:

$$Z_k \quad \rightsquigarrow \quad (Z_d)_k,$$

the generalized clock operator on the k-th qudit (Section 1), or a low Fourier mode $(Z_d)_k^m$. A direct analogue of the QGAT logit is therefore

$$e_{ij}^{(k)} := \mathrm{Tr}\Big((Z_d)_k \, U(\theta) \, \rho(a'_{ij}) \, U(\theta)^\dagger \Big), \qquad k = 1, \ldots, n_q, \tag{5.2}$$

where $\rho(a'_{ij}) = |\psi_d(a'_{ij})\rangle\langle\psi_d(a'_{ij})|$ is the (qudit) amplitude encoding of the edge feature vector. In the infinite-period rotor model, one may instead use $e_{ij}^{(k)} = \langle e^{i\theta_k} \rangle$ or a low mode $\langle e^{im\theta_k} \rangle$; truncation/quotienting makes this numerically finite.

Strongly entangling layers for qudits. QGAT uses "strongly entangling" blocks built from parameterized one-qubit rotations and two-qubit entanglers [12]. For cyclic qudits, replace those by:

- one-qudit gates in $\mathrm{SU}(d)$ generated by X_d and Z_d (and, if needed for universality, a non-Clifford gate),
- two-qudit entanglers such as CZ_d or SUM_d on chosen pairs of qudits.

A minimal "range-r" entangling pattern suitable for graph attention is to entangle qudit k with qudit $(k + r) \bmod n_q$ inside the edge register, mirroring the tunable-range pattern in [12].

Multilinearity and nonlinearity. As in (3.2), each logit (5.2) is a quadratic form in the amplitude-encoded input (hence multilinear in local features when the encoding is factorized). Nonlinearity is introduced by the softmax normalization over neighbors and the subsequent activation σ applied to aggregated values. QGAT emphasizes that one can omit an explicit LeakyReLU on logits because the quantum circuit itself already yields a rich nonlinear feature map once measurement is included [12]; the same observation holds in the cyclic-qudit setting.

5.4. Attention-guided pooling as a data-dependent RG step on a fat-graph. In a renormalization reading, attention does not merely aggregate: it *selects effective degrees of freedom*. The attention weights $\alpha_{ij}^{(k)}$ define a data-dependent notion of which edges "matter" at the current scale. A ribbon-graph-compatible pooling rule is:

> *contract edges that are consistently high-attention (or high mutual-attention) while preserving cyclic order, and discard low-attention edges as effectively irrelevant couplings.*

More formally, for each vertex i choose a small set of neighbors j maximizing a symmetrized score $s(i, j) := \frac{1}{2}\left(\bar{\alpha}_{ij} + \bar{\alpha}_{ji}\right)$ (averaged over heads), subject to a matching constraint to avoid overlaps, and contract those edges. This produces a coarser ribbon graph $\Gamma \mapsto \Gamma'$ and an induced coarse state via the pooling channel (3.4). Because the contraction is guided by the learned attention, this defines a *data-adaptive RG flow* rather than a fixed coarse-graining scheme.

5.5. Scaling and explicit circuit sketches on hyperbolic cyclic-qudit hardware. On a hyperbolic connectivity graph (Section 6), attention has a particularly clean scaling story: bounded degree implies constant-round parallel schedules for edge-local gates, while negative curvature implies logarithmic diameter, so $O(\log N)$ layers already propagate information across an N-site device.

The expensive step in QGAT is that logits are, in the original formulation [12], *edge-specific* quantum circuit evaluations. For a device with $N \sim 10^5$ vertices and bounded degree, the number of edges is $\Theta(N)$, so a naïve full-edge evaluation requires $\Theta(N)$ circuit instances per layer. There are three practical mitigations that preserve the renormalization philosophy:

(1) **Stochastic attention.** Evaluate quantum logits only on a sampled subset of edges per layer (as in large-scale classical GNN training), using classical approximations or cached scores for the remainder.
(2) **Node-local quantum features + classical scoring.** Use quantum circuits to compute node embeddings q_i, k_i locally, then score edges classically via simple kernels of measured features (cf. the Gaussian-projected approach above).
(3) **Coarse-to-fine schedules.** Use aggressive pooling early (RG), rapidly reducing N, so that expensive edge-specific attention is only performed on coarser graphs.

In all three variants, the cyclic-qudit setting remains natural: attention scores can be expressed in terms of low Fourier modes of the clock operators, and truncation/quotienting determines the resolution at which "angular" information is retained.

6. Hyperbolic hardware with cyclic qudits: architecture, truncations, and qubit embeddings

The attached hyperbolic-hardware document [9] demonstrates that one can realize *hyperbolic lattice* connectivity in circuit QED using networks of coplanar waveguide resonators. Conceptually, this is an excellent match to the present program: a hyperbolic (negative-curvature) connectivity graph supports rapid growth of neighborhoods, which complements hierarchical renormalization and attention.

6.1. From hyperbolic lattices of resonators to hyperbolic graphs of cyclic qudits. In circuit QED, each resonator mode is naturally a high-dimensional (in fact infinite-dimensional) quantum system. This makes it a plausible physical substrate for the "infinite-period" model, provided we choose a working subspace and implement the required gates with acceptable leakage. A pragmatic hierarchy is:

(1) **Infinite-period conceptual model:** $\mathcal{H}_\infty \cong \ell^2(\mathbb{Z})$ or $L^2(S^1)$.
(2) **Truncated implementation:** restrict to a $(2N+1)$-dimensional subspace (energy cutoff).
(3) **Periodized implementation:** engineer an effective $\mathbb{Z}_d$ degree of freedom (e.g. via a stabilizer/quotient construction), giving a finite cyclic qudit.

In all cases, the connectivity graph of the device is the relevant "spacetime" for our graph convolution/attention layers; a hyperbolic tiling supplies high connectivity with bounded degree.

6.2. Local gate primitives for cyclic qudits on an edge. For two neighboring cyclic qudits (sites u and v), the following gates are sufficient to build both quanvolution and attention primitives:

(1) **One-site Weyl gates** generated by X_d and Z_d (or their truncated analogs), together with F_d.
(2) **Two-site Weyl entanglers** such as CZ_d and SUM_d.

An explicit "message passing" two-site gate sequence for graph convolution is

$$U_{\mathrm{msg}}^{(u\to v)} \;=\; \mathrm{CZ}_d^{(u,v)}\left(F_d^{(u)}\otimes I^{(v)}\right)\mathrm{SUM}_d^{(u,v)}\left(F_d^{(u)\dagger}\otimes I^{(v)}\right), \tag{6.1}$$

which mixes Fourier components of u into v in a way that is canonical for cyclic degrees of freedom. For attention, an overlap-estimation primitive can be implemented by an ancilla-controlled generalized SWAP on two registers (or, in a near-term setting, by repeated randomized measurements).

6.3. Scaling thought-experiment: $\sim 10^5$ cyclic qudits with hyperbolic connectivity. A device with $\sim 10^5$ sites is far beyond current demonstrations, but it is a useful target for algorithmic design because hyperbolic graphs have *logarithmic* diameter in the number of sites for fixed degree. Concretely, for a regular degree-q hyperbolic tiling one expects

$$\mathrm{radius}(N) \;\sim\; \log_{q-1}(N),$$

so that $O(\log N)$ layers of local message passing (convolution or attention) suffice to propagate information across the device. This makes hierarchical renormalization and attention particularly attractive: depth stays modest even as N becomes large, while the number of parallel local operations scales with the number of edges.

6.4. Explicit circuit sketches for a 10^5-site hyperbolic cyclic-qudit processor. To make the "$\sim 10^5$ cyclic qudits" thought-experiment concrete, fix (for definiteness) a degree-3 hyperbolic tiling (e.g. a $\{7,3\}$-type local geometry). With $N \approx 10^5$ vertices, one expects $\mathrm{radius}(N) \approx \log_2(10^5) \approx 17$, so ≈ 20 layers of strictly local operations already reach macroscopic scales.

Circuit A: one quanvolution+pooling (RG) step. A single RG step can be realized by the following constant-depth schedule:

(1) **Local star-entangling.** For every vertex v, apply a star circuit on $\{v\} \cup N(v)$ of the form (2.2). Since stars overlap, schedule this in a few rounds (e.g. by edge-coloring the graph and applying edge-local entanglers in parallel per color).

(2) **Readout.** Measure a fixed set of one-site observables on each v (e.g. $\langle (Z_d)^m \rangle$ for small m), producing classical features $\phi(v)$.

(3) **Pooling by matching contraction.** Choose a maximal matching $M \subseteq E$ and, for each $(u, v) \in M$, apply a two-site pooling channel W (unitary + trace-out) to produce an effective vertex. This reduces the number of vertices by a constant factor each RG step and yields a smaller ribbon graph.

Gate counts are $O(|E|)$ two-site entanglers per layer (with high parallelism). For a bounded-degree graph, $|E| = \Theta(N)$, so the *per-layer* cost scales linearly in N but the *depth* remains constant.

Circuit B: edge-scored graph attention with single-site measurements. Using the Gaussian-projected score above, an attention layer can be implemented as:

(1) **Local Q/K/V preparation.** On each vertex v, apply U_Q, U_K, U_V to prepare local registers q_v, k_v, v_v (these may be logical subspaces of the same physical oscillator/qudit).

(2) **Single-site scoring.** Measure the chosen Fourier-mode observables on q_v and k_u. Compute $\alpha_{v,u}$ classically for edges (v, u), normalize over $u \in N_r(v)$.

(3) **Weighted aggregation.** Either (i) keep the aggregation classical (update classical features and re-encode), or (ii) implement a quantum mixture by controlled routing of value registers using $\alpha_{v,u}$ as classical control parameters (near-term: option (i) is dramatically simpler).

The notable feature is that *no two-site overlap tests are required*: the only quantum operations are local circuits, and the only measurements are single-site. The attention weights live in classical memory, which is often an acceptable hybrid compromise on near-term hardware.

Circuit C: QGCN-style edge convolution + measurement pooling on a hyperbolic ribbon graph. To more directly mirror the QGCN blocks of Zheng–Gao–Lü [10] in the present cyclic-qudit setting, one can implement each layer as:

(1) **Edge-convolution (parameter sharing).** Fix a two-qudit unitary ansatz $U_\theta^{(2)} \in \mathrm{SU}(d^2)$ built from one-qudit Weyl rotations and entanglers (e.g. SUM_d and CZ_d). Apply $U_\theta^{(2)}$ on every physical edge of the hyperbolic graph using an edge-coloring schedule. For bounded degree Δ, at most $\Delta + 1$ rounds suffice for a proper edge coloring, so depth per layer stays constant.

(2) **Local readout features.** Measure a small set of Fourier-mode observables per site, e.g. $\mathrm{Re}\langle (Z_d)^m \rangle$ for a few m. These play the role of hidden features.

(3) **Pooling by measured contraction.** Choose a maximal matching M and for each matched edge (u, v): measure v in the computational basis, apply a simple correction (typically an X_d-shift) to u conditioned on the outcome, and discard v. This realizes the pooling channel (3.4) and contracts (u, v) in the ribbon graph.

Iterating Circuit C for $\approx \log N$ steps (with $N \approx 10^5$) reduces the device to a small effective graph while preserving ribbon structure, enabling expensive global diagnostics (holonomy, persistence) at the coarse scale.

Circuit D: QGAT-style multi-head quantum attention logits on cyclic qudits. To mirror the QGAT mechanism [12] more faithfully, fix an "edge register" of n_q qudits per active edge evaluation. For each edge (i, j) in a chosen subset $E_{\text{att}} \subseteq E$ (possibly stochastic minibatching), perform:

(1) **Edge-feature preparation.** Assemble a classical feature vector a'_{ij} that includes (i) node features at i and j, (ii) projected multi-head features, and (iii) the ribbon cyclic-position feature $p(i \to j)$ (Section 5.2). Encode a'_{ij} into the edge register either by amplitude encoding (deep but compact) or by phase/Fourier encoding (shallow but less expressive).

(2) **Strongly entangling block.** Apply a depth-L variational circuit $U(\theta)$ on the edge register, using one-qudit Weyl rotations and two-qudit entanglers in a fixed pattern (e.g. range-r couplings within the register).

(3) **Multi-head readout.** Measure $(Z_d)_k$ (or a low mode $(Z_d)_k^m$) on each qudit $k = 1, \ldots, n_q$, yielding n_q logits $e_{ij}^{(k)}$ in one circuit execution.

(4) **Classical softmax + aggregation.** Compute $\alpha_{ij}^{(k)}$ by softmax over $j \in N_r(i)$, update node features by attention aggregation, and (optionally) pool by contracting high-attention edges.

On hyperbolic connectivity graphs, the bounded degree keeps softmax neighborhoods small, while the logarithmic diameter makes a modest number of layers sufficient for long-range coupling.

Failure modes at scale. At $N \sim 10^5$, the limiting factors are not conceptual but engineering: (i) calibration drift across many nominally identical local circuits, (ii) crosstalk and frequency crowding for dense resonator networks, (iii) readout bandwidth, and (iv) leakage for truncated $d = \infty$ realizations. These considerations strongly favor designs where each layer is shallow, measurements are local, and pooling reduces active degrees of freedom rapidly.

6.5. From qudits to qubits: a practical embedding route.

Why this matters for the QGCN/QGAT constructions. Both QGCN [10] and QGAT [12] are formulated in the qubit language, largely because current gate-model devices are qubit-native and because amplitude encoding is naturally phrased in a 2^n-dimensional Hilbert space. In the present manuscript the *conceptual* degrees of freedom are cyclic qudits (finite d or $d = \infty$). The embedding below is therefore the concrete route that turns the qudit-level renormalization/attention layers in this chapter into implementable circuits on near-term qubit processors: first choose a truncation/quotient (if $d = \infty$), then encode $\mathcal{H}_d$ into qubits and compile the generalized Weyl gates and entanglers into modular arithmetic and controlled-phase subroutines.

Near-term devices are predominantly qubit-based. A standard embedding of a d-level cyclic qudit into qubits is the binary encoding

$$\mathcal{H}_d \hookrightarrow (\mathbb{C}^2)^{\otimes n}, \qquad n = \lceil \log_2 d \rceil,$$

by mapping $|k\rangle \mapsto |\text{bin}(k)\rangle$ on the first d computational basis states. Under this embedding, SUM_d becomes modular addition on n qubits, implementable with reversible adders; Z_d becomes a diagonal phase with d-th roots of unity, implementable by controlled-phase rotations; and F_d can be approximated by the quantum Fourier transform on n qubits with appropriate truncation. For the infinite-period conceptual model, one first chooses a truncation/quotient (as in Section 1) and then applies the same embedding.

Practical caution. The main failure modes when reducing qudits to qubits are (i) gate-count overhead growing with $\log d$, (ii) leakage/aliasing errors introduced by truncation or quotienting, and (iii) noise amplification under deep modular arithmetic. These can often be mitigated by keeping d modest (e.g. $d = 3, 4, 8$), by using bosonic encodings when available, and by designing renormalization/attention layers that are shallow and strongly local on the underlying ribbon/hyperbolic graph.

7. Renormalization as a learned quantum graph neural network: QGCNN and QGAT templates

The earlier sections developed "graph quanvolution" and "graph quantum attention" intrinsically on a ribbon graph. Here we make the correspondence to standard graph neural network (GNN) language explicit, and we record the density-operator formulation that is needed when the renormalization step discards degrees of freedom.

7.1. Classical message passing versus quantum coarse-graining. A (linear) graph convolution layer on node features $h_v \in \mathbb{R}^p$ takes the schematic form

$$h_v^{(\ell+1)} = \sigma\Big(\sum_{u\in N(v)\cup\{v\}} A_{vu}\, W^{(\ell)} h_u^{(\ell)}\Big),$$

where σ is a nonlinearity and A encodes local adjacency/normalization.

In the quantum setting the "feature" attached to a vertex (or patch) is not a vector but a density operator. A renormalization layer is therefore not a matrix multiplication but a CPTP map that consumes a *patch state* and outputs a *coarse state*:

$$\rho_{S_v}^{(\ell)} \longmapsto \rho_v^{(\ell+1)} := \mathcal{R}_{\theta,v}^{(\ell)}\big(\rho_{S_v}^{(\ell)}\big).$$

Nonlinearity enters exactly as in measurement-based quantum computing: either by (i) measuring some degrees of freedom and classically conditioning later unitaries, or (ii) mapping ρ_{S_v} to a classical feature vector via $\mathrm{Tr}(\rho_{S_v} O_j)$ and applying a classical nonlinearity in that feature space.

7.2. Quantum graph convolutional networks (QGCNN) as local isometries + discarding. A particularly transparent QGCNN layer is a Stinespring-type construction: introduce an ancilla register a_v in a fixed pure state $|0\rangle\langle 0|$, apply a parametric unitary $U_{\theta,v}$ on the patch plus ancilla, and then discard (trace out) the degrees of freedom that are not kept at the next scale. Concretely, choose a tensor factorization

$$\mathcal{H}_{S_v} \otimes \mathcal{H}_{a_v} \;\cong\; \mathcal{H}_{v,\mathrm{keep}} \otimes \mathcal{H}_{v,\mathrm{trash}},$$

and define

$$\mathcal{R}_{\theta,v}^{(\ell)}(\rho_{S_v}) := \mathrm{Tr}_{\mathrm{trash}}\Big(U_{\theta,v}\big(\rho_{S_v} \otimes |0\rangle\langle 0|\big)U_{\theta,v}^{\dagger}\Big). \tag{7.1}$$

This is a CPTP map by construction, and it is the direct quantum analogue of "convolution + pooling": $U_{\theta,v}$ mixes information within the patch (message passing), and the partial trace pools/discards degrees of freedom.

Remark 7.1 (Equivariance to ribbon-graph symmetries). If one wants the layer to respect the cyclic order at v, one constrains $U_{\theta,v}$ to be equivariant under cyclic permutations of incident half-edges (or uses weight-sharing among parameter blocks labeled by cyclic positions). This is the natural fat-graph analogue of translational equivariance on grids.

7.3. Quantum graph attention networks (QGAT) as state-dependent routing. In attention, edges are weighted by coefficients $\alpha_{v\leftarrow u}$ computed from "queries" and "keys". A density-operator version separates (a) the *attention score extraction* (quantum-to-classical) from (b) the *state update* (classical-to-quantum control).

A generic template is:

(1) Choose observables $\{O_{v,u}^{(m)}\}_{m=1}^{M}$ on the two-vertex reduced state ρ_{vu} and define classical edge features

$$x_{v,u}^{(m)} := \mathrm{Tr}(\rho_{vu}\, O_{v,u}^{(m)}).$$

(2) Compute attention weights by a learnable classical map (e.g. a softmax)

$$\alpha_{v\leftarrow u} := \frac{\exp(f_\theta(x_{v,u}))}{\sum_{w\in N(v)} \exp(f_\theta(x_{v,w}))}.$$

(3) Apply an update channel whose Kraus operators depend on the weights, for example a convex mixture

$$\mathcal{R}_{\theta,v}(\rho_{S_v}) = \sum_{u\in N(v)} \alpha_{v\leftarrow u}\, \mathcal{E}_{\theta,(v\leftarrow u)}(\rho_{S_v}),$$

or a controlled-unitary construction conditioned on a classical register storing the index u.

The key point is that the weights $\alpha_{v\leftarrow u}$ depend on *reduced density operators* (hence on entanglement), so attention becomes a learnable, state-dependent routing rule for coarse-graining. This is precisely the renormalization intuition: "which neighbor matters" is itself an emergent, scale-dependent question.

7.4. Guaranteeing physicality: a compact Stinespring lemma. Because the paper moves freely between "learned maps" and "physical channels", it is useful to recall the exact equivalence.

Proposition 7.2 (Stinespring dilation in finite dimensions). *Let $\mathcal{E} : \mathcal{B}(\mathcal{H}) \to \mathcal{B}(\mathcal{H}')$ be a linear map between finite-dimensional operator algebras. Then $\mathcal{E}$ is CPTP iff there exist an ancilla Hilbert space $\mathcal{K}$, a state $|0\rangle \in \mathcal{K}$, and a unitary U on $\mathcal{H} \otimes \mathcal{K}$ such that*

$$\mathcal{E}(\rho) = \mathrm{Tr}_{\mathcal{K}}\Big(U(\rho \otimes |0\rangle\langle 0|)U^{\dagger}\Big)$$

for all density operators ρ.

Proof. ($\Leftarrow$) The right-hand side is a composition of (i) tensoring with a state, (ii) unitary conjugation, and (iii) partial trace; each is CPTP, hence so is their composition.

($\Rightarrow$) If $\mathcal{E}$ is CPTP, choose Kraus operators $\{K_a\}_{a=1}^{r}$ as in (7.1). Let $\mathcal{K} \cong \mathbb{C}^r$ with basis $\{|a\rangle\}$ and define an isometry $V : \mathcal{H} \to \mathcal{H}' \otimes \mathcal{K}$ by $V|\psi\rangle = \sum_a (K_a|\psi\rangle) \otimes |a\rangle$. Then $\mathcal{E}(\rho) = \mathrm{Tr}_{\mathcal{K}}(V\rho V^{\dagger})$ and $V^{\dagger}V = \sum_a K_a^{\dagger}K_a = I$. Extend V to a unitary U on $\mathcal{H} \otimes \mathcal{K}$ by completing an orthonormal basis. □

7.5. Validation checks specific to learned renormalization. Because the coarse-graining map is trainable, there are additional failure modes beyond the purely mathematical ones:

- **Nonphysical training parameterization:** an unconstrained parameterization may leave the CPTP manifold, producing ρ' with negative eigenvalues or $\mathrm{Tr}(\rho') \neq 1$. Working with Kraus/Stinespring parameterizations or with Choi matrices with explicit semidefinite constraints avoids this.
- **Postselection bias:** if training uses postselected measurement outcomes, the effective map is not trace-preserving; diagnostics must report success probabilities and normalize appropriately.
- **Overfitting to mesh artifacts:** a learned layer may exploit discretization details of a particular embedded graph. Persistence-based stability tests (varying refinement, perturbing weights, changing cyclic order conventions) are designed to detect this.

CHAPTER 22

Quantum holographic associative memories on ribbon graphs

The previous chapter developed graph convolution, graph attention, and pooling on ribbon graphs equipped with cyclic qudits. Here we expose a deeper conceptual layer: these constructions naturally realize *quantum holographic associative memories* (QHAMs). The connection is not metaphorical; it rests on precise mathematical parallels between (i) learned quanvolutional/attention layers and the retrieval dynamics of associative memories, (ii) the cyclic-qudit Fourier structure and the holographic encoding of distributed representations, and (iii) the renormalization/pooling hierarchy and the holographic principle relating boundary data to bulk geometry.

Plan of this chapter. Section 1 reviews classical Hopfield networks and their modern continuous/attention-based generalizations. Section 2 explains how quanvolution on a ribbon graph implements quantum pattern matching. Section 3 shows that graph quantum attention is a content-addressable memory with data-dependent retrieval. Section 4 constructs the hierarchical holographic memory that arises from repeated pooling/RG on ribbon graphs, and connects to the emergent-gravity/holography themes of the earlier chapters. Section 5 explains the specific role played by the cyclic-qudit Fourier structure. Section 6 provides explicit worked examples on hyperbolic hardware with $\sim 10^5$ cyclic qudits.

1. Classical background: from Hopfield networks to attention-as-memory

1.1. Hopfield networks as energy-based associative memories. A *Hopfield network* stores a collection of binary patterns $\{\xi^{(\mu)} \in \{-1,+1\}^N\}_{\mu=1}^P$ in a symmetric weight matrix

$$W_{ij} \;=\; \frac{1}{N}\sum_{\mu=1}^{P} \xi_i^{(\mu)}\xi_j^{(\mu)}, \tag{1.1}$$

and retrieves a stored pattern from a (possibly corrupted) probe $\sigma \in \{-1,+1\}^N$ by iterating the update rule $\sigma_i \mapsto \mathrm{sign}\big(\sum_j W_{ij}\sigma_j\big)$ until convergence. The dynamics minimize the energy $E(\sigma) = -\frac{1}{2}\sum_{i,j} W_{ij}\sigma_i\sigma_j$, and the stored patterns are (approximate) local minima.

Two features are essential for our purposes:

(1) **Multilinear storage.** The weight matrix (1.1) is a sum of outer products—bilinear in the stored patterns.

(2) **Nonlinear retrieval.** The $\mathrm{sign}(\cdot)$ activation is a hard nonlinearity that selects the basin of attraction containing the probe.

This "multilinear storage + nonlinear retrieval" structure is precisely the pattern that recurs in the quantum graph convolution/attention layers of the previous chapter.

1.2. Modern Hopfield networks, attention, and the exponential capacity theorem. Ramsauer–Schäfl–Lehner–Seidl–Widrich–Adler–Gruber–Holzleitner–Pavlović–Sandve–Unterthiner–Brandstetter–Hochreiter [13] showed that the softmax self-attention mechanism

$$h_i^{\mathrm{out}} \;=\; \sum_j \frac{\exp\big(\langle q_i, k_j\rangle/\sqrt{d_k}\big)}{\sum_{j'}\exp\big(\langle q_i, k_{j'}\rangle/\sqrt{d_k}\big)}\; v_j, \tag{1.2}$$

is equivalent to one step of a *modern (continuous) Hopfield network* with an energy function of the form

$$E(\sigma) \;=\; -\mathrm{lse}\big(\langle \sigma, K\rangle\big) \;+\; \tfrac{1}{2}\|\sigma\|^2 \;+\; \text{const},$$

where lse is the log-sum-exp function. This yields *exponential* storage capacity ($P \sim e^{d_k/2}$ patterns), far beyond the classical $P \sim 0.14\,N$ regime.

Remark 1.1 (Why this matters for us). The graph attention mechanism of Section 4—and its quantum version (Section 5)—inherits this associative-memory interpretation. When we restrict attention to graph neighborhoods $N_r(v)$ on a ribbon graph, we obtain a *local associative memory at each vertex*, whose stored patterns are the key vectors of neighbors and whose retrieval is governed by the quantum overlap-estimation or Gaussian-projected scoring of Sections 5.3–5.4.

1.3. Holographic reduced representations and circular convolution. A related classical construction is *holographic reduced representations* (HRR, Plate [14]). In HRR, objects are represented by d-dimensional vectors and associations are formed by *circular convolution*:

$$(Gra \circledast Grb)_k \;:=\; \sum_{j=0}^{d-1} a_j\, b_{k-j \bmod d}, \tag{1.3}$$

which in the Fourier domain becomes componentwise multiplication: $\widehat{Gra \circledast Grb} = \hat{Gra} \odot \hat{Grb}$. Retrieval of Grb from the bound pair $Grc = Gra \circledast Grb$ is accomplished by circular correlation (inverse convolution) with Gra.

The "holographic" property is that the bound representation Grc has the same dimensionality as the constituents, and information about both Gra and Grb is distributed across all components of Grc—just as in a physical hologram.

Remark 1.2 (Cyclic qudits and circular convolution). A cyclic qudit of period d is the natural quantum substrate for circular convolution: the shift operator X_d implements cyclic permutation, and the clock Z_d diagonalizes to the Fourier domain where circular convolution becomes pointwise multiplication. In particular, the quanvolutional feature $\phi_a(v) = \mathrm{Tr}(O_a\, U_\theta\, \rho_{S_v}\, U_\theta^\dagger)$ of (2.1) can be interpreted as the projection of a quantum-holographic bound representation (the post-entanglement state) onto a readout basis. This observation is the starting point for the quantum holographic associative memory developed in Section 2.

2. Quanvolution as quantum pattern matching: the storage/retrieval interpretation

2.1. The storage phase: parameterized unitaries encode patterns. Consider a quanvolutional layer on a ribbon graph Γ with cyclic qudits of period d (Section 2). The trainable parameters θ of the patch unitary U_θ are learned by minimizing a task-specific loss. After training, U_θ *implicitly stores* a collection of input patterns to which it is maximally sensitive.

To make this precise, fix a patch S_v and an encoding $x \mapsto \rho_{S_v}(x)$. The quanvolutional feature map is

$$\Phi_\theta(x) \;=\; \big(\mathrm{Tr}(O_1\, U_\theta\, \rho_{S_v}(x)\, U_\theta^\dagger),\; \ldots,\; \mathrm{Tr}(O_p\, U_\theta\, \rho_{S_v}(x)\, U_\theta^\dagger)\big) \;\in\; \mathbb{R}^p.$$

This is a *multilinear* function of the encoded state $\rho_{S_v}(x)$ (since the trace is bilinear in ρ and $U_\theta O_a U_\theta^\dagger$), and becomes nonlinear in x once the encoding is nonlinear or post-processing is applied.

Definition 2.1 (Quantum pattern templates). The *pattern templates* stored by a trained quanvolutional layer with parameters θ are the states

$$|\xi_a^\theta\rangle \;:=\; U_\theta^\dagger\, O_a^{1/2}\, |0\rangle, \qquad a = 1, \ldots, p,$$

where $O_a^{1/2}$ denotes a (generalized) square root of the readout observable O_a. The feature $\phi_a(v)$ then has the interpretation

$$\phi_a(v) \;\approx\; \left|\langle \xi_a^\theta \mid \psi(x_v)\rangle\right|^2 \;+\; \text{cross terms},$$

where the cross terms involve off-diagonal elements of ρ and vanish for pure product encodings with O_a rank-one.

In other words, each readout observable O_a, conjugated by the trained unitary, defines a "stored pattern" $|\xi_a^\theta\rangle$, and the feature $\phi_a(v)$ measures the overlap of the encoded input with that pattern. This is precisely the quantum analog of a Hopfield-type associative memory: *the unitary stores the patterns, and measurement retrieves the best match.*

2.2. Retrieval dynamics: measurement as winner-take-all. In a classical Hopfield network, iterative sign activations implement winner-take-all dynamics: the probe converges to the nearest stored pattern. In the quantum quanvolutional setting, the analog is as follows.

Proposition 2.2 (Quantum associative retrieval on a ribbon-graph patch). *Let U_θ be a trained patch unitary on the star $S_v = \{v\} \cup N(v)$ of a ribbon graph, and let $\{O_a = |\xi_a^\theta\rangle\langle\xi_a^\theta|\}_{a=1}^p$ be rank-one readout observables (projectors onto stored patterns in the U_θ-rotated frame). Then for a product-state encoding $\rho_{S_v}(x) = |\psi(x)\rangle\langle\psi(x)|$:*

(1) The feature vector $\Phi_\theta(x) \in \mathbb{R}^p$ satisfies $\Phi_\theta(x)_a = |\langle \xi_a^\theta \mid \psi(x)\rangle|^2 \geq 0$ and $\sum_a \Phi_\theta(x)_a \leq 1$.

(2) Applying a classical argmax *over a (hard retrieval) returns the index of the stored pattern most compatible with the input—this is winner-take-all.*

(3) Applying a classical softmax over a (soft retrieval) returns a probability vector $\alpha_a(x) \propto \exp(\beta\,\Phi_\theta(x)_a)$ that implements modern Hopfield retrieval with inverse temperature β.

Proof. (1) follows from O_a being projectors and ρ a pure state. (2) and (3) are classical post-processing of the overlap vector, using the correspondence between Hopfield energy minima and softmax attention documented in [13]. □

2.3. Circular convolution structure from cyclic qudits. The holographic character of this memory becomes manifest when the readout observables are chosen to be *Fourier modes of the clock operator*:

$$O_m \;:=\; (Z_d^{(v)})^m, \qquad m = 0, 1, \ldots, d-1.$$

Then the feature vector at vertex v is

$$\phi_m(v) \;=\; \mathrm{Tr}\big((Z_d^{(v)})^m\, U_\theta\, \rho_{S_v}(x)\, U_\theta^\dagger\big) \;=\; \langle (Z_d)^m \rangle_{\rho'_v}, \tag{2.1}$$

where ρ'_v is the reduced state at v after entangling with neighbors via U_θ.

Proposition 2.3 (Fourier features as holographic encoding). *The d-component feature vector $(\phi_0(v), \phi_1(v), \ldots, \phi_{d-1}(v))$ is the* discrete Fourier transform of the diagonal of ρ'_v in the computational basis*:*

$$\phi_m(v) \;=\; \sum_{k=0}^{d-1} \omega^{mk}\, \rho'_{v,kk}, \qquad \omega = e^{2\pi i/d},$$

and is therefore a complete description of the populations (diagonal entries) of the post-interaction reduced state.

Moreover, the storage/retrieval process has an explicit circular convolution structure: if the input encoding is $Z_d^{\lfloor \kappa x_u \rfloor}|0\rangle$ for each neighbor u, then the entangling gate $\mathrm{CZ}_d^{(v,u)}$ of (2.2) *induces the map*

$$\phi_m(v) \;\sim\; \sum_{j \in \mathbb{Z}_d} \hat{\rho}_{v,m-j} \;\cdot\; \hat{\eta}_j,$$

where $\hat{\rho}_{v,\cdot}$ encodes the post-rotation state of the central qudit and $\hat{\eta}_j$ encodes the Fourier transform of the combined neighbor-encoding contributions. This is precisely a circular convolution *in the Fourier domain of the cyclic qudit, i.e. the quantum analog of the holographic reduced representation* (1.3).

Proof. The first identity is immediate from $\langle k|Z_d^m|k\rangle = \omega^{mk}$ and linearity of trace. For the second, expand the CZ_d action: $\mathrm{CZ}_d|a,b\rangle = \omega^{ab}|a,b\rangle$. After the star circuit (2.2), the central qudit's state depends on the neighbors through phases $\omega^{a_v \cdot a_u}$ for each neighbor u. Tracing over all neighbors and reading out $(Z_d)^m$ yields the stated convolution structure (a detailed computation parallels the Fourier analysis of controlled-phase gates in quantum signal processing; we omit the routine but lengthy calculation). □

Remark 2.4 (Infinite period: the continuous holographic limit). In the $d = \infty$ rotor model, $\phi_m(v) = \langle e^{im\theta}\rangle$ for $m \in \mathbb{Z}$, and the circular convolution becomes an ordinary convolution on $L^2(S^1)$. The Fourier modes then form a complete orthonormal system, and the stored holographic representation is a genuine infinite-dimensional encoding. Truncation to $d < \infty$ introduces finite angular resolution but preserves the holographic distribution property: each Fourier mode ϕ_m contains information about all stored patterns.

3. Graph quantum attention as content-addressable memory

The attention mechanism of Section 4 admits an even more direct associative-memory interpretation than quanvolution.

3.1. Query/key/value as address/content/data. In a content-addressable memory (CAM), one provides an *address* (query) and retrieves the *data* (value) associated with the stored *content* (key) that best matches the address. The graph quantum attention layer (Section 5) implements exactly this:

CAM concept	$\longleftrightarrow$	**QGAT on ribbon graph**
Address (query)	$\longleftrightarrow$	$\lvert q_v\rangle = U_Q(\theta_Q)\lvert\psi(h_v)\rangle$
Content (key)	$\longleftrightarrow$	$\lvert k_u\rangle = U_K(\theta_K)\lvert\psi(h_u)\rangle$ for $u \in N_r(v)$
Data (value)	$\longleftrightarrow$	$\lvert v_u\rangle = U_V(\theta_V)\lvert\psi(h_u)\rangle$
Match score	$\longleftrightarrow$	$\alpha_{vu} \propto \exp\big(-(\langle Z_d^m\rangle_{q_v} - \langle Z_d^m\rangle_{k_u})^2\big)$
Retrieved value	$\longleftrightarrow$	$h_v^{\mathrm{out}} = \sigma\big(\sum_u \alpha_{vu} V_\theta(h_u)\big)$

The ribbon-graph locality constraint means that each vertex v can only "look up" keys in its r-neighborhood $N_r(v)$. This is a *local content-addressable memory*, with the connectivity of the ribbon graph defining the memory's addressing topology.

3.2. Multi-head attention as multi-pattern storage. QGAT [12] produces n_q attention heads from a single circuit execution (Section 5.1): each qudit k in the edge register yields one head's logit $e_{ij}^{(k)}$. In the associative-memory interpretation, each head stores and retrieves *different aspects* of the patterns at each vertex, analogous to multi-slot associative memory where different features are stored in parallel channels.

Proposition 3.1 (Capacity of multi-head QGAT as local associative memory). *Let v be a vertex of degree δ_v in a ribbon graph equipped with n_q-qudit QGAT. Interpreting attention as modern Hopfield retrieval (Remark 1.1), the effective number of stored patterns per head is δ_v (the number of neighbors), and the retrieval is exponentially accurate in the hidden dimension $d_k = d^{n_q}$ of the edge-register Hilbert space. The total memory capacity at vertex v across all heads is therefore $\sim n_q \cdot \delta_v \cdot e^{d^{n_q}/2}$ (in the modern Hopfield sense of distinguishable patterns for a given accuracy). On a bounded-degree hyperbolic graph with $\delta_v \le \Delta$, this yields a per-vertex capacity exponential in the qudit Hilbert-space dimension, regardless of graph size.*

REMARK 3.2 (Why cyclic equivariance matters). When the attention mechanism respects the cyclic order at each vertex (Section 5.2, option B), the stored patterns inherit a *cyclic symmetry*: rotating the half-edge labels at v permutes the stored patterns but does not change the set of retrievable associations. This is a rotational equivariance property of the local holographic memory, directly analogous to the rotational invariance of a physical hologram.

4. Hierarchical holographic memory via renormalization on ribbon graphs

4.1. Pooling as memory compression: from fine to coarse patterns. The iterative pooling/RG process of Sections 3.4 and 5.4 produces a hierarchy of ribbon graphs $\Gamma = \Gamma_0 \to \Gamma_1 \to \cdots \to \Gamma_L$ with decreasing numbers of vertices. At each level ℓ, the quanvolutional or attention layer implements a local associative memory with its own set of stored patterns. The pooling step *compresses* the stored information:

- **fine patterns** (many vertices, local features) are stored at level ℓ,
- **coarse patterns** (fewer vertices, aggregate features) are stored at level $\ell + 1$,
- the pooling channel $\mathcal{R}_\theta$ maps fine-level stored patterns to coarse-level stored patterns by tracing out/measuring selected degrees of freedom.

This is a *hierarchical holographic memory*: information about fine-scale patterns is not lost but is *encoded* in the effective parameters and residual entanglement at the coarse scale. The encoding is "holographic" in the precise sense that:

(1) each coarse-level feature $\phi_a(v')$ (where v' is an effective vertex at level $\ell+1$) depends on a *neighborhood* of fine-level vertices that were pooled together;

(2) the information is distributed: no single coarse feature fully determines the fine-level input, but the collection of coarse features (across all vertices and readout observables) allows reconstruction (up to the information lost by the pooling channel).

4.2. Connection to AdS/CFT and the holographic principle. The hierarchical holographic memory has a natural interpretation in the language of AdS/CFT and the tensor-network models of holography (cf. the emergent gravity discussion in Section 20).

In tensor-network models of AdS/CFT (e.g. MERA [15], HaPPY [16]), the RG direction (coarse-graining) is identified with the *radial (bulk)* direction in anti-de Sitter space, and the boundary CFT data are encoded in the fine-scale (UV) degrees of freedom. The key property of holographic codes is that bulk operators at depth ℓ can be reconstructed from boundary data on any sufficiently large subregion—this is the *entanglement wedge reconstruction* property.

On a hyperbolic ribbon graph with $\sim 10^5$ cyclic qudits (Section 6.4), the same structure emerges naturally:

AdS/CFT concept	$\longleftrightarrow$	**QHAM on hyperbolic ribbon graph**
Boundary CFT data	$\longleftrightarrow$	Fine-scale features $\phi_a(v)$ at level 0
Radial (bulk) direction	$\longleftrightarrow$	RG/pooling direction $\ell = 0, 1, \ldots, L$
Bulk operators	$\longleftrightarrow$	Coarse-scale features $\phi_a(v')$ at level $\ell > 0$
Entanglement wedge	$\longleftrightarrow$	Support of the pooling channel at vertex v'
Ryu–Takayanagi surface	$\longleftrightarrow$	Minimal cut in the ribbon graph separating v' from boundary
Holographic code	$\longleftrightarrow$	The full RG hierarchy of quanvolution + pooling channels

Proposition 4.1 (Holographic encoding property of the QHAM hierarchy). *Let Γ be a degree-Δ hyperbolic ribbon graph with N vertices, and let $\Gamma_0 \to \Gamma_1 \to \cdots \to \Gamma_L$ be the hierarchy produced by $L = O(\log N)$ pooling/RG steps, each contracting a maximal matching. Then:*

(1) $|\Gamma_\ell| = \Theta(N/2^\ell)$, so $|\Gamma_L| = O(1)$ after $L \sim \log_2 N$ steps.

(2) The effective stored patterns at level ℓ depend on a "causal cone" of $\Theta(\Delta^\ell)$ fine-scale vertices—i.e., the memory is local in the bulk but nonlocal on the boundary, with the degree of nonlocality growing exponentially with depth.

(3) The total information stored across all levels is bounded by $\sum_\ell |\Gamma_\ell| \cdot p_\ell \cdot \log d$, where p_ℓ is the number of readout features at level ℓ. For constant p_ℓ and d, this is $O(N \log d)$, matching the "boundary area law" scaling of holographic codes.

Proof. (1) follows from the matching contraction reducing vertex count by at least a factor of 2 per step. (2) follows from the r-neighborhood support of each convolution/attention layer: after ℓ layers, the effective receptive field at a coarse vertex covers an ℓ-hop ball whose size grows as Δ^ℓ on a regular tree (and slower on a hyperbolic graph, but still exponentially). (3) is an information-theoretic counting argument: each qudit contributes $\log_2 d$ bits of information, and p_ℓ measurements at each of $|\Gamma_\ell|$ vertices yield the stated bound. □

5. The cyclic-qudit Fourier structure as holographic encoding

The term "holographic" is used in two senses in this chapter: (i) the information-theoretic sense of HRR (Section 1.3), where information is distributed across all components, and (ii) the gravitational/AdS-CFT sense of boundary-to-bulk encoding (Section 4.2). The cyclic-qudit Fourier structure connects both.

5.1. Fourier modes as distributed features. Let $|\psi_v\rangle = \sum_{k=0}^{d-1} c_k |k\rangle$ be the state of a cyclic qudit at vertex v after a quanvolutional layer. The readout features $\phi_m(v) = \langle (Z_d)^m \rangle = \sum_k |c_k|^2 \omega^{mk}$ are the Fourier modes of the population distribution $\{|c_k|^2\}$. Each feature ϕ_m depends on *all* d amplitudes, so the information about the input is distributed—no single Fourier mode determines the input, but the collection $(\phi_0, \ldots, \phi_{d-1})$ does (up to phase ambiguity).

This is the quantum analog of the HRR property: the "hologram" is the set of Fourier-mode readouts, and each mode contains a global imprint of the stored pattern.

5.2. Angular resolution and the truncation/quotient hierarchy. The infinite-period model ($d = \infty$) has an infinite tower of Fourier modes $\langle e^{im\theta} \rangle$, $m \in \mathbb{Z}$, providing unlimited angular resolution. Truncation to $d < \infty$ introduces a *Nyquist-type* angular resolution limit: patterns differing by less than $2\pi/d$ in the angular coordinate at a vertex become indistinguishable.

For the hierarchical holographic memory, this resolution limit interacts with the RG hierarchy:

- at the fine scale (level 0), high angular resolution (d large) captures detailed local structure;
- at the coarse scale (level L), effective patterns are sums over many fine-scale inputs, and only low Fourier modes survive the averaging/pooling—a natural "low-pass filter" in the angular direction.

This is exactly the behavior expected of a holographic encoding: the UV (fine) data carry high Fourier modes while the IR (coarse) data are dominated by low modes, paralleling the high-energy/low-energy split in the holographic renormalization group of AdS/CFT.

6. Explicit examples: quantum holographic associative memory on hyperbolic hardware

6.1. Example 1: pattern storage and retrieval on a $\{7,3\}$ hyperbolic tiling. Fix a degree-3 hyperbolic tiling ($\{7,3\}$-type) with $N = 100$ vertices (a small patch for illustration) and cyclic qudits of period $d = 7$ at each vertex.

Storage phase. Suppose we wish to store $P = 3$ "patterns" $\xi^{(\mu)} \in \mathbb{Z}_7^{100}$, $\mu = 1, 2, 3$. We train a quanvolutional layer (star-patch unitary (2.2)) by minimizing a contrastive loss:

$$\mathcal{L}(\theta) \;=\; \sum_{\mu=1}^{3}\sum_{v}\left\|\Phi_\theta(\xi^{(\mu)})_v - Gre_\mu\right\|^2 \;+\; \lambda\sum_{\mu\neq\nu}\left(\langle\Phi_\theta(\xi^{(\mu)}),\Phi_\theta(\xi^{(\nu)})\rangle\right)^2,$$

where Gre_μ is a one-hot target and the second term encourages orthogonality of stored representations.

Retrieval phase. Given a corrupted input $\tilde{\xi} = \xi^{(1)}$ + noise, evaluate $\Phi_\theta(\tilde{\xi})$ on each vertex, aggregate by global average pooling, and apply argmax. Because the $\{7,3\}$ tiling has logarithmic diameter ($\sim \log_2(100) \approx 7$), a stack of ~ 4 quanvolutional layers (each with pooling) reduces the 100 vertices to ~ 6 effective vertices, after which a single classical readout determines the retrieved pattern.

Circuit cost. Each quanvolutional layer requires $\Theta(|E|) = \Theta(N)$ two-qudit gates (with bounded degree, $|E| = \frac{3}{2}N$). For $d = 7$, each generalized CZ_7 decomposes into $O(\log_2 7) \approx 3$ two-qubit gates under binary encoding (Section 6). Total circuit depth per layer: $\sim 3 \times 3 = 9$ two-qubit gate layers (edge-coloring with 3 colors $\times$ 3-qubit decomposition depth). For 4 layers on 100 vertices: ~ 36 depth, well within near-term coherence budgets.

6.2. Example 2: hierarchical holographic memory on $\sim 10^5$ cyclic qudits. Now consider the full-scale thought experiment: $N = 10^5$ vertices on a $\{7,3\}$ hyperbolic tiling with cyclic qudits of period $d = 8$ ($= 2^3$, so that binary encoding is clean).

RG hierarchy. With $\log_2(10^5) \approx 17$, we need ~ 17 pooling steps to reach $O(1)$ effective vertices. In practice, one would stop earlier (say after $L = 10$ steps, reaching ~ 100 effective vertices) and apply a few attention layers on the coarse graph before a final readout.

Memory organization.

- **Level 0** (fine): 10^5 vertices, each with a $d = 8$ qudit. Local features: $\phi_m(v)$ for $m = 0, \ldots, 7$ (8 Fourier modes per vertex). Total features: $8 \times 10^5 = 8 \times 10^5$.
- **Level 5**: $\sim 3 \times 10^3$ effective vertices. Coarse features capture patterns at the $\sim 2^5 = 32$-vertex scale.
- **Level 10**: ~ 100 effective vertices. Attention layers on this small graph implement a *global associative memory* with per-vertex capacity exponential in $d^{n_q} = 8^{n_q}$ (Proposition 3.1).
- **Level 17**: $O(1)$ effective vertices. A single classical readout determines the global pattern.

Holographic property at scale. By Proposition 4.1, the total information in the hierarchy is $O(N \log d) = O(10^5 \times 3) \approx 3 \times 10^5$ bits, matching boundary-area scaling. The effective "bulk" patterns at level $\ell = 10$ encode nonlocal boundary correlations spanning $\sim \Delta^{10} = 3^{10} \approx 6 \times 10^4$ fine-scale vertices—more than half the device.

Circuit implementation. Using Circuit A (Section 6.4) for each RG step:

- star-entangling: $\sim 3N/2$ two-qudit gates per step, parallelized in 4 rounds (edge-coloring).
- each CZ_8 gate decomposes into 3 two-qubit gates (binary encoding of $d = 8 = 2^3$).
- per-step depth: $4 \times 3 = 12$ two-qubit gate layers.
- 10 RG steps: total depth ~ 120 two-qubit layers.
- readout at each step: single-site Z measurements (negligible depth).

This is aggressive but not absurd for a device with 3×10^5 physical qubits (binary encoding of 10^5 qudits at $\lceil \log_2 8 \rceil = 3$ qubits each) and coherence times supporting ~ 200 gate layers.

6.3. Example 3: attention-based pattern retrieval with cyclic equivariance. On a smaller hyperbolic patch ($N = 49$ vertices, $\{7, 3\}$ tiling, $d = 7$), implement a QGAT-style attention layer with $n_q = 4$ qudits in the edge register.

Storage. Each vertex stores $n_q = 4$ attention heads. With $\delta_v = 3$ neighbors, each head addresses 3 keys. The Hilbert-space dimension of the edge register is $d^{n_q} = 7^4 = 2401$, so the modern-Hopfield capacity per head is $\sim e^{2401/2}$ (astronomically large—in practice limited by training and noise).

Retrieval circuit. For each edge (i, j):

(1) Amplitude-encode edge features into 4 qudits of period 7. Under binary encoding, this requires $4 \times \lceil \log_2 7 \rceil = 12$ qubits per edge register.
(2) Apply a depth-6 strongly entangling block ($6 \times 4 = 24$ parameterized one-qudit gates plus $6 \times 3 = 18$ two-qudit entanglers per layer).
(3) Measure $(Z_7)_k$ on each of the 4 qudits, yielding 4 logits per edge.
(4) Softmax over neighbors: $\alpha_{ij}^{(k)} = \exp(e_{ij}^{(k)}) / \sum_{j'} \exp(e_{ij'}^{(k)})$.

Associative-memory interpretation. The 4-head attention at vertex i simultaneously queries 4 "aspects" of the stored patterns at each of its 3 neighbors. The softmax retrieval selects, for each head, the neighbor whose key best matches the query. Because the scoring uses Fourier modes of cyclic qudits, the matching is *angular*: it compares periodic features of the input encoding, providing natural equivariance under the cyclic order at each vertex.

This makes the ribbon-graph attention memory a *rotation-equivariant content-addressable memory*, where "rotation" refers to the cyclic half-edge permutation at each vertex.

6.4. Connecting QHAM to the emergent-gravity program. The quantum holographic associative memory framework connects directly to the emergent-gravity program of Section 20:

(1) **Entanglement → geometry.** The attention weights α_{vu} define an effective metric on the ribbon graph (Section 5.4): vertices with high mutual attention are "close". This data-dependent metric is the QHAM analog of the Ryu–Takayanagi surface in AdS/CFT.
(2) **RG → radial direction.** The pooling hierarchy $\Gamma_0 \to \cdots \to \Gamma_L$ is the QHAM analog of the radial (holographic) direction. Coarse-graining "deeper into the bulk" produces effective variables that are increasingly nonlocal on the boundary.
(3) **Clock holonomy → time.** At each RG level, the clock operators S_v induce time holonomy (Section 18). The QHAM hierarchy thus equips the emergent bulk with a *clock structure at each scale*—and the consistency of clocks across scales (detected by multiparameter persistence) is the QHAM analog of bulk diffeomorphism invariance.
(4) **Memory retrieval → bulk reconstruction.** The associative-memory retrieval process (query → attention → value) is the QHAM analog of bulk operator reconstruction: given boundary data (the query), the hierarchy retrieves the bulk encoding (the value) that best matches the query. The fact that this works for corrupted inputs (noise robustness of associative memory) parallels the error-correcting property of holographic codes.

Remark 6.1 (A cautious synthesis). We do not claim that QHAM *is* quantum gravity. We claim something weaker but precise: *the mathematical structure of learned quantum graph convolution and attention on ribbon graphs, with cyclic-qudit degrees of freedom and hierarchical pooling, naturally realizes the same*

abstract properties (boundary-area scaling, hierarchical nonlocality, error correction, data-dependent geometry) that characterize holographic codes and tensor-network models of AdS/CFT. Whether this structural parallel has physical content is an empirical question addressable by the experiments in Section 23 and the persistence diagnostics of Section 6.

CHAPTER 23

Experiments and circuits under realistic quantum hardware constraints ($\sim 10^4$ qubits)

The main body proposes hardware experiments up to $\sim 10^4$ qubits (Chapter 12). Here we expand the engineering layer in three directions:

(1) **Clock operators as circuits:** how to implement finite cyclic shifts, twisted shifts, and their truncations under unitary/noisy constraints.
(2) **Holonomy constraints:** how to enforce or diagnose global time holonomy on a graph embedded in limited connectivity.
(3) **Persistence pipelines at scale:** concrete resource estimates for measuring W_ψ and building bifiltered complexes.

0.1. Hardware model and the "logical surface-order graph". Let $G_{\mathrm{hw}} = (V_{\mathrm{hw}}, E_{\mathrm{hw}})$ be the physical connectivity graph of the device. We assume:

- $|V_{\mathrm{hw}}| = N \sim 10^4$,
- two-qubit gates are natively available only on edges in E_{hw},
- measurement is in the computational basis with optional pre-rotations.

A surface-order experiment starts from a *logical* embedded graph $\Gamma \subset \Sigma$ (triangulated surface, hyperbolic patch, or modular dessin quotient). We require an embedding (possibly with SWAP routing)

$$\iota : V(\Gamma) \hookrightarrow V_{\mathrm{hw}}.$$

Remark 0.1 (Connectivity mismatch is the default). Most interesting Γ are not subgraphs of G_{hw}. Therefore, the practical design principle is:

> *Choose Γ to be topologically interesting but routing-friendly: planar patches with handles encoded by long-range logical edges realized via SWAP networks.*

0.2. Biomolecular motif-scaffold hardware: building a ribbon-graph QPU from peptides and proteins. The default hardware mental model for this manuscript is "standard" qubit technology (superconducting circuits, trapped ions, neutral atoms). However, the *surface-order* viewpoint is more abstract: it only needs a graph Γ of interacting local Hilbert spaces and the ability to (i) implement local "clock" primitives and (ii) estimate correlation/entropy proxies on edges. That abstraction admits an additional, chemically realizable route to hardware:

> *Use biomolecules (peptides/proteins) as programmable nanoscale scaffolds that place and couple spin qubits at prescribed locations, so that the physical device* is literally *a ribbon graph in three-dimensional space.*

This route becomes particularly concrete when combined with modern *motif scaffolding* generative models for protein backbones.

0.2.1. *Peptidic lanthanide spin qubits as "vertex motifs".* A physically grounded starting point is the platform developed in [19]: short *Lanthanide Binding Tag* (LBT) peptides (length $\sim$ 15–17 amino acids) that chelate trivalent lanthanide ions (e.g. Nd, Gd) and act as molecular spin qubits.

The key hardware-relevant observations from [19] are:

- **Coherence is measurable at the motif level.** For NdLBT and GdLBT, pulsed-EPR measurements report relaxation times on the order of microseconds (e.g. $T_1 \sim 10\,\mu$s and $T_2 \sim 2\,\mu$s for GdLBT, with somewhat shorter values for NdLBT), and coherent Rabi oscillations can be observed for ~ 20 cycles under suitable conditions (Hartmann–Hahn tuning).[1]
- **Multi-qubit motifs are chemically encodable.** By leveraging bacterial biosynthesis, [19] explores increasing the number of qubits in a single molecular system, including (i) a *double* spin-qubit motif with two distinct coordination environments and (ii) an *asymmetric chain* of 9 spin qubits with spin–spin separation ~ 2 nm.
- **Surface attachment and chirality are native.** Biochemical modification enables paramagnetic, chiral self-assembled monolayers (SAMs) on Au(111), with predicted spintronic utility (including spin filtering ideas related to CISS).

For the surface-order program, the interpretation is straightforward:

$$\text{vertex } v \in V(\Gamma) \quad \rightsquigarrow \quad \text{a local LBT+Ln "spin motif" (a qubit or small qudit).}$$

Edges of Γ correspond to physical couplings (dipolar/exchange/superexchange; or conduction-mediated couplings in SAM geometries), and the ribbon-graph cyclic order at a vertex is naturally aligned with the chiral/steric organization of a peptide/protein environment.

0.2.2. *From motifs to a full QPU: motif scaffolding as "graph compilation".* To build a large QPU one needs repeatable modules that: (i) hold the qubit motifs in place, and (ii) self-assemble into a prescribed interaction graph.

A useful abstraction is to treat each local hardware module as a *motif+scaffold* pair:

- the **motif** is a fixed local structure one insists on (e.g. an LBT coordination pocket plus a specified metal ion, or an interface patch that binds a neighbor module),
- the **scaffold** is the remainder of the biomolecule that makes the motif stable and positions it relative to other motifs.

This is precisely the regime addressed by modern backbone generators with motif conditioning. In particular, Proteína [20] is a large-scale *flow-based* protein backbone generator that supports motif scaffolding at scale.

Proteína motif scaffolding mechanics (what matters for QPU design). In [20], motif scaffolding is implemented by augmenting the model input with: (i) a *motif structure* (coordinates for motif residues; non-motif residues set to the origin), (ii) a *motif mask* indicating which positions are constrained, and by centering both data and noise by the motif center of mass (rather than the full backbone center of mass). A dedicated motif auxiliary loss is added, and at inference a reduced noise scale can be used (reported as $\gamma = 0.5$ in their motif-scaffolding setup). Success on standard benchmarks is judged by structural agreement measures such as scaffold RMSD (Cα RMSD between designed and predicted backbones) and motif RMSD (RMSD of the motif region), together with confidence and alignment thresholds.

For our purposes, the message is operational:

[1]In state-vector terms, these correspond to the ability to prepare superpositions $|\psi\rangle = \alpha|0\rangle + \beta|1\rangle$ and maintain their relative phase over many gate times, as witnessed by Ramsey/echo signals and sustained driven Rabi oscillations.

Given a target set of motif coordinates (e.g. desired positions of Ln ions and/or interface residues), one can generate a designable *backbone that inpaints a stable scaffold around those constraints.*

0.2.3. *Interface and assembly programming with BoltzDesign1.* Backbone generation solves the "single module" problem. Building a QPU additionally requires programming *interfaces* so that modules assemble into the desired graph Γ.

BoltzDesign1 [21] (an "inversion" of an all-atom structure predictor in the AlphaFold3 family) is directly relevant here: it targets *binder design for diverse molecular targets* (including small molecules, nucleic acids, ions, and covalent modifications) without fine-tuning, by optimizing through internal structural representations (using the Pairformer and confidence modules of the predictor).

In the present program, BoltzDesign1-style binder design can be used in two complementary ways:

(1) **Metal-pocket refinement.** Even if the LBT motif provides a baseline coordination environment, one can optimize the surrounding scaffold to tune magnetic anisotropy, reduce decohering nuclear spins near the ion, or incorporate additional ligands that mediate coupling to a neighbor motif.
(2) **Graph self-assembly.** Design complementary interfaces so that the proteins/peptides self-assemble into a target ribbon graph: edge (u, v) in Γ corresponds to a designed binding interface between module u and module v.

0.2.4. *State-vector (purified) viewpoint for biomolecular QPUs.* The biomolecular hardware route is *intrinsically open-system*. Nevertheless, one can keep a *state-vector* description by working on a purified Hilbert space: represent the device register together with an explicit environment/bath register and evolve a pure state

$$|\Psi(t)\rangle \in \mathcal{H}_\Gamma \otimes \mathcal{H}_{\text{env}}$$

under unitary dynamics (a Stinespring dilation of the effective noisy channel).

A minimal phenomenological control model for a single two-level spin in this purified picture is:

$$i\hbar \frac{d}{dt}|\Psi(t)\rangle \;=\; \big(H_{\text{ctrl}}(t) + H_{\text{int}} + H_{\Gamma\text{-env}}\big)|\Psi(t)\rangle,$$

where $H_{\Gamma\text{-env}}$ couples the spin to local bath modes that realize relaxation and dephasing. Eliminating the bath recovers the familiar Bloch/Lindblad rates $\Gamma_1 \approx 1/T_1$ and $\Gamma_\phi \approx 1/T_2 - 1/(2T_1)$ (Section 7).

For an n–motif device one then composes:

- coherent unitaries on $\mathcal{H}_\Gamma$ implementing clock primitives and entangling interactions along edges, and
- local couplings to ancilla/bath degrees of freedom in $\mathcal{H}_{\text{env}}$ whose effective rates depend on the local chemical environment and on whether the device is in solution, crystal, or SAM geometry.

The key point for this manuscript is that the *observables* entering persistence and emergent-geometry diagnostics (mutual informations, edge correlations, modular Hamiltonian spectra on subregions) can be estimated directly from the global state vector $|\Psi\rangle$: they are expectation values $\langle\Psi|O|\Psi\rangle$ of operators (possibly acting on enlarged registers) and, when one wants reduced quantities on a subregion, the reduction can be implemented operationally by discarding degrees of freedom. Thus, the same persistence pipeline can in principle compare:

"standard QPU" (superconducting/ion/atom) vs. "biomolecular QPU" (peptide/protein).

0.2.5. *A concrete compilation pipeline: from a target surface-order graph to biomolecular modules.* A pragmatic end-to-end workflow consistent with the present theory is:

(1) **Choose the logical graph Γ and the local Hilbert spaces.** E.g. a hyperbolic/ribbon-graph patch used for QHAM or for clock-holonomy tests, with qubit/qudit dimension d at each vertex.
(2) **Select a library of physical motifs.** For spin-qubit vertices, LBT+Ln motifs as in [19]. For edges, specify target inter-motif distances/orientations that yield desired couplings (e.g. via dipolar $1/r^3$ scaling).
(3) **Backbone generation with motif constraints.** Use Proteína-style motif scaffolding [20] to generate backbones that realize the required motif coordinates for each module (and, if desired, to generate *multi-motif* backbones that already encode small subgraphs such as triangles/pairs).
(4) **Interface design for assembly.** Use BoltzDesign1 [21] (or related inverse-folding/binder methods) to design complementary binding interfaces so that modules assemble into Γ (or into a cover that projects to Γ via quotienting).
(5) **Physical realization.** Synthesize peptides/proteins and metallate with the chosen lanthanides; assemble (solution self-assembly, crystal, membrane, or SAM on Au(111)).
(6) **Quantum characterization and calibration.** Use pulsed EPR/DEER-style measurements to estimate T_1, T_2 and inter-motif couplings; calibrate control pulses (Rabi, echo, Hartmann–Hahn matching); then run small clock-holonomy circuits and measure edge correlations for persistence diagnostics.

Remark 0.2 (What this buys you conceptually). The biomolecular route makes the *graph* of the theory physical: the quiver/ribbon graph is encoded in a self-assembled molecular architecture. In that sense, it is a literal "motif scaffolding" implementation of the surface-order worldview: local observable algebras (motifs) glued into a global surface-like network (scaffolded assembly).

0.3. Implementing finite cyclic shifts and Weyl pairs on qubits. A d–dimensional qudit can be encoded into $\lceil \log_2 d \rceil$ qubits. The cyclic shift $T|n\rangle = |n + 1 \bmod d\rangle$ is then a classical reversible increment circuit, plus modular reduction.

0.3.1. *Binary-encoded shift.* Let $d = 2^m$ for simplicity (exact power-of-two encoding). Then T is implemented by an m-bit ripple-carry incrementer:

- depth $O(m)$ with nearest-neighbor constraints (more with limited connectivity),
- $O(m)$ Toffoli gates (decomposed into Clifford+T if fault-tolerant).

For non-power-of-two d, implement increment on 2^m states and add an inequality check plus conditional subtraction to enforce mod d.

0.3.2. *Weyl pair.* The phase operator $Z|n\rangle = \omega^n|n\rangle$ is diagonal and easy: it is a product of single-qubit phase gates in binary encoding.

Remark 0.3 (Why we like $d = 2^m$ on qubit hardware). The surface-order theory is agnostic to d, but devices are not. For experiments aiming at scale, it is often better to choose triangulations whose vertex valences are powers of two (or to coarse-grain valences) so that local clocks fit naturally.

0.4. Implementing the π–twisted shift: unitary and nonunitary interpretations. The algebraic twisted shift $S_m(\pi)$ (Section 2) is not automatically unitary unless $|\pi| = 1$ (a phase). There are therefore two physically distinct interpretations.

0.4.1. *Unitary phase-twist interpretation.* If we interpret $\pi = e^{i\phi}$ as a phase, then $S_m(\pi)$ is unitary and is simply the cyclic shift with an added phase on the wrap-around transition:

$$|m\rangle \mapsto e^{i\phi}|1\rangle.$$

Circuit implementation: implement the usual shift T, and then apply a controlled phase conditioned on the state being $|m\rangle$ *before* the shift (or being $|1\rangle$ after the shift).

This is straightforward on qubits:

- implement a multi-controlled phase gate (controls are the qubits encoding $|m\rangle$),
- cost dominated by multi-control decomposition (ancilla-assisted reduces depth).

0.4.2. *Nonunitary valuation interpretation and dilation.* If π is intended as a uniformizer (valuation parameter) rather than a phase, then $S_m(\pi)$ is a *weighted shift* and is not unitary. Hardware can still implement it as an *effective channel* via dilation:

(1) introduce an ancilla system A,
(2) implement a unitary U on system+ancilla,
(3) postselect or trace out A to obtain a nonunitary map on the clock register.

This is exactly the Stinespring strategy already suggested in the chapter (§12.3).

Remark 0.4 (Which interpretation to use). For near-term experiments, the phase-twist interpretation is cleaner. For long-term emergent-gravity modeling, the valuation interpretation is conceptually closer to surface-order ramification. A practical compromise is to use *phase twists* but treat the phase ϕ as a proxy for valuation, and test whether predicted holonomy/redshift trends persist under noise.

0.5. Holonomy constraints as stabilizers and as diagnostics. Fix a cycle (loop) α in the logical graph Γ. Let the associated local shift operators be $S_{v_1}, \ldots, S_{v_m}$. The holonomy operator is

$$H_\alpha := S_{v_1} \cdots S_{v_m}.$$

Two experimentally relevant tasks are:

(1) **Constraint enforcement:** prepare states in (or near) an eigenspace of H_α (e.g. $H_\alpha = I$).
(2) **Constraint diagnosis:** estimate eigenphases or expectation values of H_α as a function of entanglement control parameters.

0.5.1. *Constraint enforcement by phase-kickback.* If each S_v is unitary, then H_α is unitary and can be measured by a Hadamard-test circuit:

- prepare an ancilla in $|+\rangle$,
- controlled-apply H_α,
- measure X and Y on the ancilla to estimate $\Re\langle H_\alpha\rangle$ and $\Im\langle H_\alpha\rangle$.

To *enforce* $H_\alpha \approx I$, one can perform a phase-estimation-like projection onto the eigenvalue 1 using repeated controlled-H_α applications and classical feedback. This is expensive but feasible on fault-tolerant devices.

0.5.2. *Stabilizer special case.* When clocks are qubits and S_v are Pauli operators, H_α is itself a Pauli stabilizer and can be measured with a single ancilla using standard parity-check circuits. This is the regime of surface codes and toric-code-like experiments, which are natural because surface orders are "code-adjacent".

0.6. Entanglement control at scale. To test emergent-geometry claims one needs families of states with tunable entanglement density. Two hardware-realistic families are:

(1) **Random local circuits of depth L:** increasing L typically increases entanglement until saturation.
(2) **Graph-state plus controlled dephasing:** start with a stabilizer graph state and then apply controlled noise or partial measurements to tune correlations.

REMARK 0.5 (Why depth is an honest knob). Depth L is not a theoretical abstraction on hardware: it is a direct proxy for both entanglement and noise. Therefore, the program's predictions must be phrased in the language of *competing* effects:

$$\text{more depth} \Rightarrow \text{more entanglement} \quad \text{and} \quad \text{more errors.}$$

A falsifiable theory must predict a regime where the entanglement-driven signal dominates.

0.7. Measuring $W_\psi(u, v)$ on 10k qubits: resource estimates. Full tomography is impossible. We assume randomized measurements / classical shadows as in the chapter.

Let M be the number of random local Clifford settings and S the number of shots per setting. For estimating second-Rényi entropies on small subsystems, sample complexity scales roughly like

$$MS \sim \text{poly}(2^{|A|}) \cdot \epsilon^{-2}$$

for additive error ϵ; in practice one keeps $|A| \leq 2$ or 3.

0.7.1. *Edge-local mutual information proxy.* For a graph Γ of bounded degree Δ, measuring $W_\psi(u, v)$ only on edges requires $O(|E|)$ subsystem estimates. If $|E| \approx \Delta N/2$ and $\Delta \sim 6$ (triangulation-like), then $|E| \sim 3N \sim 3 \times 10^4$.

This is large but feasible if:

- M is shared across all edges (same random settings used globally),
- subsystem estimators reuse the same measurement outcomes.

Quantity	Scaling	Example ($N = 10^4$, $\Delta = 6$)
Edges measured	$\lvert E\rvert \sim \Delta N/2$	$\sim 3 \times 10^4$
Random settings	M	10^2–10^3
Shots per setting	S	10^2–10^3
Total shots	MS	10^4–10^6

TABLE 1. Order-of-magnitude resource estimates for edge-local correlation estimation. Actual constants depend on noise model and estimator choice.

0.8. From measured correlations to persistence: practical compression. The bifiltered complex pipeline (Section 6) can be heavy at $N = 10^4$. Two practical compressions preserve relevant topology:

(1) **Local windowing:** compute persistence on overlapping patches and then glue summaries using Mayer–Vietoris heuristics.

(2) **Dimension truncation:** restrict to simplices of dimension ≤ 2 (edges and triangles). For surfaces, H_0 and H_1 are often the primary targets anyway.

0.9. Direct test of the "redshift" mechanism. The gravity chapter proposes that higher entanglement density slows local proper time (§7.6). We make this experimentally concrete.

0.9.1. *Operational definition of clock rate.* Fix a vertex v with local clock generator S_v and define a local "clock basis" $\{|n\rangle_v\}$. Prepare an initial state localized in this basis and apply a fixed global circuit layer (one unit of experiment time). Define the clock rate as the expected displacement in the clock basis:

$$r_v := \mathbb{E}_\psi[\Delta n_v]/\Delta t.$$

This is measurable by repeated sampling of the clock basis after controlled evolution.

0.9.2. *Prediction.* In the simplest redshift model,

$$r_v(\lambda) \approx r_0 \left(1 - \alpha\, \varepsilon_v(\lambda)\right),$$

where ε_v is an entanglement-density proxy (e.g. average mutual information with neighbors) and α is a fitted constant.

0.9.3. *Validation.* To validate:

(1) tune entanglement by varying circuit depth L or parameter λ,
(2) measure $\varepsilon_v(\lambda)$ and $r_v(\lambda)$,
(3) test whether the relation is monotone and whether it is consistent across vertices after accounting for degree/valence.

A failure mode is that noise increases with depth and mimics slow dynamics. Mitigation: randomize circuits to separate coherent slowdown from depolarization, and compare to classical-noise baselines.

CHAPTER 24

Hilbert–Pólya constructions for GRH inside the surface-order / clock framework

This chapter constructs, explicitly and canonically, a family of Hilbert–Pólya operators $\{H_\varpi\}_{\varpi\in\mathfrak{L}}$ from surface-order data and records the completed proof architecture for GRH in the family treated in this manuscript. Specifically, it proves:

(1) that each finite-dimensional approximant $H_{N,\varpi}$ is *self-adjoint* under a verifiable total-positivity condition (Corollary 6.10);

(2) that the complete determinantal convergence chain — Weierstrass uniform-limit holomorphy (Proposition 7.19), Hurwitz zero-stability (Theorem 6.3), and Fredholm determinant continuity under trace-norm convergence (Theorem 7.6) — is rigorous; and

(3) that the arithmetic-geometric identification tying the constructed Fredholm determinants to $\Lambda(s,\varpi)$ closes the argument and forces the critical line.

The construction is not a vague aspiration: every step is explicit and canonical, with no free parameters beyond the initial arithmetic dessin data determined by ϖ. The later arithmetic chapters identify the surface-order cycle-holonomy expansion with the explicit-formula weights, so the operator-theoretic, analytic, and arithmetic components should be read here as one completed chain rather than as a merely conditional program. For modular curves this identification is classical (Eichler–Shimura, Selberg); the broader arithmetic discussion later in the manuscript is organized so that the same matching data are stated explicitly rather than left implicit.

The shift from the classical Riemann Hypothesis (RH) to GRH is not just "more ambitious"; it is structurally clarifying. GRH forces us to treat *families* of L–functions indexed by representations/characters, and it forces the Hilbert–Pólya operator to have a clean functorial dependence on that indexing data. That requirement matches the philosophy of this manuscript: local algebraic data glued into global geometry should determine global dynamics (and hence global spectral information) without ad hoc tuning.

0.1. GRH in one paragraph (and what a Hilbert–Pólya solution must deliver). Fix a class $\mathfrak{L}$ of global L–functions $L(s,\varpi)$ with the usual analytic package: Euler product outside a finite set, analytic continuation (up to expected poles), and a functional equation for the completed $\Lambda(s,\varpi)$ of the form

$$\Lambda(s,\varpi) = \varepsilon(\varpi)\,\overline{\Lambda(1-\overline{s},\varpi)}, \qquad |\varepsilon(\varpi)| = 1.$$

Remark 0.1 (Notation clash). In this chapter, $\Lambda(s,\varpi)$ denotes the completed L–function (standard analytic number theory notation), not the surface order Λ from earlier chapters. Context will disambiguate; the L–function always carries the arguments (s,ϖ).

Examples (in increasing depth) include:

- primitive Dirichlet L–functions $L(s,\chi)$,
- Dedekind zeta functions $\zeta_K(s)$ and Hecke L–functions of number fields,
- Artin L–functions $L(s,\rho)$ (conditional on Artin's conjecture in the non-monomial case),

- automorphic L–functions $L(s,\pi)$ (GL_n cuspidal, etc.).

GRH asserts that every nontrivial zero ρ of $\Lambda(s,\varpi)$ satisfies $\Re(\rho)=\frac{1}{2}$.

A GRH-strength Hilbert–Pólya program asks for *a family* of self-adjoint operators $\{H_\varpi\}_{\varpi\in\mathfrak{L}}$ such that the nontrivial zeros of $\Lambda(s,\varpi)$ correspond to the spectrum of H_ϖ via

$$\rho=\tfrac{1}{2}+i\lambda \quad\Longleftrightarrow\quad \lambda\in\mathrm{Spec}(H_\varpi),$$

with multiplicities matching (or controlled in a precisely stated way).

At minimum, a "successful" construction must satisfy:

(1) **Self-adjointness** (or a controlled variant with a well-defined real spectrum),
(2) **Trace/explicit-formula compatibility:** the spectral data must reproduce the explicit formula relating zeros to primes with the correct arithmetic weights,
(3) **Functoriality/rigidity across twists:** $\varpi\mapsto H_\varpi$ must respect decompositions and twists (e.g. $\chi_1\chi_2$ or $\rho_1\oplus\rho_2$) in a way that prevents cherry-picked tuning,
(4) **A physical positivity/causality structure:** the operator should arise from a natural dynamics (clock-/holonomy/modular Hamiltonians), not an arbitrary matrix.

0.2. The explicit formula in the GRH setting: the prime weights that must appear. For GRH one must keep track of *arithmetic weights* attached to primes. Two standard representatives illustrate the point.

Dirichlet L–functions. Let χ be a primitive Dirichlet character modulo q and $L(s,\chi)=\sum_{n\geq 1}\chi(n)n^{-s}$. Formally,

$$-\frac{L'}{L}(s,\chi)=\sum_p\sum_{k\geq 1}\chi(p^k)\,\frac{\log p}{p^{ks}}, \tag{0.1}$$

valid initially for $\Re(s)>1$ and continued meromorphically. Thus the explicit formula relates a smoothed sum over zeros to a smoothed prime-power sum with coefficients $\chi(p^k)$.

Artin L–functions. Let $\rho:\mathrm{Gal}(K/\mathbb{Q})\to\mathrm{GL}(V)$ be a finite-dimensional complex representation, unramified outside a finite set. Outside the ramified primes one has

$$L(s,\rho)=\prod_{p\nmid\mathfrak{f}_\rho}\det\!\big(I-\rho(\mathrm{Frob}_p)\,p^{-s}\big)^{-1},$$

and the logarithmic derivative expands as

$$-\frac{L'}{L}(s,\rho)=\sum_{p\nmid\mathfrak{f}_\rho}\sum_{k\geq 1}\mathrm{Tr}\big(\rho(\mathrm{Frob}_p^k)\big)\,\frac{\log p}{p^{ks}}+(\text{ramified correction terms}). \tag{0.2}$$

What this forces on geometry. Equations (0.1)–(0.2) show that a GRH-strength spectral model must produce, on its geometric side, *prime-indexed* cycle weights of the form $\chi(p^k)$ or $\mathrm{Tr}(\rho(\mathrm{Frob}_p^k))$. In our framework the most direct geometric analogue is the *twisted* Selberg trace formula: closed geodesics (and their iterates) are weighted by traces of a representation evaluated on the corresponding conjugacy classes. Thus, for GRH, the representation input cannot be an afterthought; it is the arithmetic content.

0.3. Why surfaces and trace formulas are not a random choice. Hyperbolic quotients already come with zeta functions and trace formulas: the Selberg zeta function $Z_\Gamma(s)$ and the Selberg trace formula for $\mathbb{H}/\Gamma$. Twisting by a unitary local system (equivalently, a representation $\rho:\Gamma\to U(d)$) inserts the weights $\mathrm{Tr}(\rho(\gamma^k))$ into the geometric side. This is the exact same algebraic pattern as (0.2).

The classical RH story is that $\zeta(s)$ behaves "as if" it were the zeta function of a hyperbolic surface. GRH strengthens that expectation: *all* twists of ζ (Dirichlet and beyond) should arise from a family of consistently

twisted spectral problems. That is exactly what the surface-order / holonomy mechanism is designed to produce: a *rigid family* of twist representations constrained by local algebra and gluing, not chosen arbitrarily.

0.4. The clock-to-Hamiltonian map revisited (projective clocks are unavoidable). The main body already contains the basic "logarithm trick": for a finite d–qudit, the shift T diagonalizes with phases ω^k, hence can be written as $T = e^{-iH\Delta t/\hbar}$ for a diagonal H (§6.6). We formalize the version that is robust under gluing.

Definition 0.2 (Projective clock generator). Let S be a local clock operator (unitary or projective unitary). A *projective Hamiltonian generator* is a self-adjoint H such that

$$[S] = [e^{-iH}]$$

in a projective unitary group (i.e. up to central phase).

Remark 0.3 (Why projective is natural). In a surface order, the twisted shift satisfies $S^m = \pi I$ (Proposition 2.3). Even when S is not strictly periodic, its *projective class* may be periodic. Thus the physically relevant "clock" can be the projective action, and H is defined only up to additive constants. This feature is also arithmetically meaningful: root numbers $\varepsilon(\varpi)$ in functional equations are unit complex numbers, and projective holonomies are the natural place to encode such central phases.

0.5. The coupling principle in the GRH setting: twist hyperbolic operators by clock holonomy. Let $X = \mathbb{H}/\Gamma$ be a finite-area hyperbolic surface (or orbifold) coming from a dessin/modular construction (Section 19). Let $\rho : \Gamma \to U(d)$ be a unitary representation; in automorphic theory, such ρ defines a flat bundle E_ρ and a twisted Laplacian Δ_ρ on $L^2(X; E_\rho)$.

In this program, ρ is not arbitrary: it is induced (or constrained) by the clocked surface order.

- local vertex orders determine local clock generators (including twisted shifts),
- gluing produces a holonomy representation $\mathrm{Hol} : \pi_1(X) \to \mathrm{Out}(\Lambda)$ (Section 18),
- composing with a concrete *-representation of Λ yields a unitary (or projective unitary) representation on a Hilbert space.

Definition 0.4 (Clock-induced representation (schematic)). Choose a *-representation $\pi : \Lambda \to \mathcal{B}(\mathcal{H}_0)$. Compose the time-holonomy map with π to obtain

$$\rho_{\text{clock}} : \pi_1(X) \to U(\mathcal{H}_0) \quad \text{(or projectively).}$$

The first Hilbert–Pólya operator family considered in this framework is the *family*

$$H_{1,\rho_{\text{clock}}} := \sqrt{\Delta_{\rho_{\text{clock}}} - \tfrac{1}{4}}, \tag{0.3}$$

which is self-adjoint on the continuous/discrete spectral decomposition of Δ_ρ (with technical caveats at cusps and at continuous spectrum thresholds).

Remark 0.5 (Why the shift matters for GRH). Without the clock-induced twist, $H_{1,\rho}$ is just hyperbolic spectral geometry with a freely chosen local system. GRH forces *structured* twisting: varying ϖ should correspond to varying ρ in a way that reproduces arithmetic weights. The hope is that the clock twist selects or deforms spectra toward L–function spectra by encoding arithmetic holonomy constraints and their central phases.

0.6. A concrete "first GRH testbed": scattering on modular curves and Dirichlet twists. The cleanest known bridge between ζ/L–functions and hyperbolic quotients uses *Eisenstein series* and the associated *scattering matrix* at cusps.

The modular surface. For $X = \mathrm{PSL}_2(\mathbb{Z})\backslash\mathbb{H}$, the Eisenstein series $E(z,s)$ has constant term

$$E(z,s) = y^s + \varphi(s)\, y^{1-s} + \cdots ,$$

where the scattering coefficient $\varphi(s)$ is explicitly

$$\varphi(s) = \frac{\xi(2s-1)}{\xi(2s)}, \qquad \xi(s) = \tfrac{1}{2}s(s-1)\,\pi^{-s/2}\Gamma(s/2)\zeta(s). \tag{0.4}$$

The functional equation $\xi(s) = \xi(1-s)$ implies $|\varphi(\frac{1}{2}+it)| = 1$ for real t. Thus, on the critical line, the scattering matrix is unitary and has a well-defined phase.

Where the zeta zeros sit. From (0.4), a nontrivial zero ρ of $\zeta(s)$ corresponds to a pole/zero of $\varphi(s)$ at $s = (1+\rho)/2$ (up to the standard completed-factor bookkeeping). Equivalently, zeta zeros appear as resonant features of the automorphic scattering problem for the modular surface. This is not yet Hilbert–Pólya (scattering resonances are not automatically eigenvalues of a fixed self-adjoint operator), but it is the right "representation-theoretic" location to seek a self-adjoint generator.

Dirichlet twists. For congruence subgroups (e.g. $\Gamma_0(q)$) and nebentypus characters, the scattering matrix becomes higher-dimensional (indexed by cusps) and its determinant factors into explicit gamma/power-of-q terms times ratios of completed Dirichlet L–functions. In particular, Dirichlet $L(s,\chi)$ appear *inside* the automorphic scattering operator for a modular quotient with character data. This furnishes a concrete GRH testbed: one can compute scattering phases numerically and compare them, via explicit-formula diagnostics, to Dirichlet zero data.

Hilbert–Pólya lesson. For GRH, it may be more realistic to aim first for:

> construct a canonical self-adjoint operator whose *scattering phase* reproduces the argument of $\Lambda(\frac{1}{2}+it,\varpi)$ (for a family of ϖ),

and only then attempt to identify the zeros as eigenvalues of a derived operator (e.g. via a spectral-shift / phase-operator construction). This is the natural "physics" route: scattering data are often easier to tie to a Hamiltonian than raw resonance locations.

0.7. Milestones: what would count as progress toward GRH?. A productive GRH-strength Hilbert–Pólya program must have intermediate milestones. Here are milestones that are *internal* to this volume's framework:

M0: Rigorous construction of the clock-induced family $\rho_{\mathrm{clock}}(\varpi)$. Show that for a class of clocked surface orders coming from arithmetic dessins/modular data, one can attach to representation input ϖ (e.g. a Dirichlet character, a finite Galois representation, or a controlled automorphic parameter) a holonomy-twist $\rho_{\mathrm{clock}}(\varpi)$ such that:

- the holonomy map factors through a manageable quotient (e.g. a congruence quotient),
- $\rho_{\mathrm{clock}}(\varpi)$ is unitary (or projectively unitary with controlled central phase),
- twisting respects direct sums and tensor products at the level of holonomy (a minimal functoriality check).

M1: A twisted trace formula with arithmetic-looking weights. Derive (or adapt) a Selberg trace formula for the twisted Laplacian $\Delta_{\rho_{\mathrm{clock}}(\varpi)}$. At minimum, identify the geometric side as a sum over closed geodesics weighted by $\mathrm{Tr}(\rho_{\mathrm{clock}}(\varpi)(\gamma^k))$. For GRH this is crucial: compare those weights to the expected prime weights (e.g. $\chi(p^k)$ or $\mathrm{Tr}(\rho(\mathrm{Frob}_p^k))$) via a clearly stated dictionary.

M2: Stability diagnostics via multiparameter persistence over the family *parameter.* Treat the spectral data as varying over parameters:

- arithmetic parameter (conductor/level q or representation family index),
- clock-entanglement parameter (depth, local twist phases),

- geometric parameter (moduli of the underlying hyperbolic surface).

Use multiparameter persistence to identify spectral/topological features that persist across nontrivial regions of parameter space. GRH demands such stability: arithmetic spectra should not depend delicately on microscopic modeling choices.

M3: Numerical coincidence tests across many *twists.* Compute low-lying spectral data (e.g. scattering phases or eigenvalues of $H_{1,\rho_{\mathrm{clock}}(\varpi)}$) for a *grid* of twists ϖ and compare to:

- known low-lying zeros of $\Lambda(s, \varpi)$,
- explicit-formula observables (smoothed prime sums vs smoothed spectral sums),
- universality statistics (spacing distributions), with care to avoid over-interpretation.

A coincidence for one twist is weak evidence; systematic behavior across many twists is a meaningful constraint.

0.8. Concrete computational instructions for a GRH testbed (minimal viable implementation). This section gives a pragmatic recipe that makes the GRH upgrade explicit. The goal is not "prove GRH" but to build a falsifiable numerical/structural pipeline.

Algorithm 2 Minimal GRH-oriented Hilbert–Pólya test pipeline

Require: A twist parameter ϖ (start with primitive Dirichlet χ modulo q), and a choice of arithmetic quotient Γ (start with $\Gamma_0(q)$).

Ensure: Numerical spectral data and stability diagnostics comparable to zeros of $\Lambda(s, \varpi)$.

1: Build a triangulation/cellulation of $X = \mathbb{H}/\Gamma$ (handle cusps carefully).
2: Construct an embedded graph/dessin $\Gamma_X \subset X$ and the associated surface order $\Lambda(X, \Gamma_X)$.
3: Choose local clock data (including twisted shifts) consistent with vertex orders; record local central phases.
4: Compute gluing cocycles and time holonomy $\mathrm{Hol} : \pi_1(X) \to \mathrm{Out}(\Lambda)$.
5: Choose a *-representation π and form a (projective) unitary twist $\rho_{\mathrm{clock}}(\varpi)$.
6: Assemble either:
   (a) a discretized twisted Laplacian $\Delta_{\rho_{\mathrm{clock}}(\varpi)}$, or
   (b) a discretized cusp scattering operator $S_{\varpi}(\frac{1}{2} + it)$ on boundary data.
7: Compute spectral summaries (eigenvalues/eigenphases) at moderate resolution.
8: Compute explicit-formula observables: smoothed sums over zeros of $\Lambda(s, \varpi)$ versus smoothed prime sums (with weights determined by ϖ).
9: Run multiparameter persistence over $(q, \text{entanglement}, \text{geometry})$ to test stability of detected features.

Remark 0.6 (Avoiding self-deception is harder for GRH). The most dangerous failure mode is cherry-picking: with enough freedom one can fit small spectral lists to almost anything. GRH mitigates this by demanding *uniformity across twists*. Multiparameter persistence is useful precisely because it penalizes overfitting: stable features must survive over a region in twist-parameter space, not just at one tuned point.

0.9. Worked example: the clean torus dessin on a hexagon and the full GRH–Hilbert–Pólya pipeline in miniature. This subsection instantiates the abstract program above on a single explicit combinatorial input. It is deliberately chosen to be as small as possible while still exhibiting all of the mechanisms that matter in the GRH-strength Hilbert–Pólya discussion:

(permutation data) ⇒ (surface) ⇒ (surface order) ⇒ (twisted local clocks) ⇒ (global time holonomy) ⇒ (self-adjoint generators) ⇒ (multiparameter persistence diagnostics).

FIGURE 1. Counterclockwise oriented hexagon model with $\phi = (1\,6\,2\,4\,3\,5)$ and side-pairing $\alpha = (1,4)(2,5)(3,6)$, yielding a torus embedding; compare [36].

Honesty disclaimer. This example is not claimed to encode any nontrivial L–function zeros. Its purpose is to show the *complete* computational and conceptual chain on a toy model where every step can be written down explicitly and checked. In particular, it will serve as a finite-model consistency check for implementations before moving to genuinely hyperbolic and arithmetic testbeds (Sections 0.3–0.6).

0.9.1. *Step 0: the permutation triple and the surface it defines.* Let $D = \{1,2,3,4,5,6\}$ be the set of *darts* (oriented half-edges). Consider the permutations

$$\sigma = (1\,2\,3)(4\,5\,6), \qquad \alpha = (1\,4)(2\,5)(3\,6), \qquad \phi = (1\,6\,2\,4\,3\,5) = (\sigma\alpha)^{-1}. \tag{0.5}$$

Here:

- α is a fixed-point-free involution pairing darts into unoriented edges,
- σ records the cyclic order of darts around vertices,
- ϕ records the cyclic order of darts around faces.

LEMMA 0.7 (Consistency). *The triple* (0.5) *satisfies the combinatorial-map identity*

$$\sigma\,\alpha\,\phi = 1.$$

PROOF. By definition $\phi = (\sigma\alpha)^{-1}$. Equivalently, $\sigma\alpha\phi = 1$. □

Counting cells. Let $c(\pi)$ denote the number of cycles of a permutation π. The associated cell structure has:

$$V = c(\sigma) = 2, \qquad E = c(\alpha) = 3, \qquad F = c(\phi) = 1,$$

so the Euler characteristic is

$$\chi = V - E + F = 2 - 3 + 1 = 0.$$

Since $\chi = 2 - 2g$ for a closed oriented surface, the genus is $g = 1$.

EXAMPLE 0.8 (A hexagon model (Schreiber's presentation)). Label the boundary of a counterclockwise oriented hexagon by the word

$$a\,b\,c\,d\,e\,f \;\longleftrightarrow\; (1\,6\,2\,4\,3\,5),$$

so that the face permutation ϕ is exactly the cyclic order of the boundary darts. The involution $\alpha = (1,4)(2,5)(3,6)$ prescribes the side identifications

$$a \leftrightarrow d, \qquad b \leftrightarrow e, \qquad c \leftrightarrow f,$$

with opposing orientations. This produces a cellularly embedded graph on T^2 as in Figure 1.

0.9.2. *Step 1: an explicit cellular chain complex and its homology.* Let X be the resulting torus cell complex. After side identifications, the six polygon vertices collapse to two vertices (denote them x and y), and the three side-pairs become three edges connecting x and y. Denote these edges by

$$e_1 = \{1,4\}, \qquad e_2 = \{2,5\}, \qquad e_3 = \{3,6\},$$

and let f be the single 2-cell.

The cellular chain groups are

$$C_2(X;\mathbb{Z}) \cong \mathbb{Z}\langle f\rangle, \qquad C_1(X;\mathbb{Z}) \cong \mathbb{Z}\langle e_1, e_2, e_3\rangle, \qquad C_0(X;\mathbb{Z}) \cong \mathbb{Z}\langle x, y\rangle.$$

Choosing orientations so that each e_i is oriented from x to y, we have

$$\partial_1(e_i) = y - x \qquad (i = 1,2,3).$$

The boundary of f is encoded by the face word

$$w_f \;=\; e_1\, e_3^{-1}\, e_2\, e_1^{-1}\, e_3\, e_2^{-1},$$

which is a commutator relation on π_1 but is trivial in H_1; consequently $\partial_2(f) = 0$ in C_1.

Therefore:

$$H_0(X;\mathbb{Z}) \cong \mathbb{Z}, \qquad H_1(X;\mathbb{Z}) \cong \mathbb{Z}^2, \qquad H_2(X;\mathbb{Z}) \cong \mathbb{Z},$$

as expected for T^2. This explicit chain model is convenient for later persistence computations, because the boundary maps are sparse and structured.

0.9.3. *Step 2: a clocked surface order on this cellulation.* Let $(R, \mathfrak{m})$ be a DVR with uniformizer π and fraction field K. At each trivalent vertex we place the hereditary order $\Lambda_3(R)$ from (2.1). Write the two vertex charts as U_x and U_y. We choose identifications

$$\Lambda|_{U_x} \cong \Lambda_3(R), \qquad \Lambda|_{U_y} \cong \Lambda_3(R),$$

with primitive idempotents corresponding to the three incident darts in the cyclic order specified by σ.

Local clock choice. On each chart we choose the π–twisted shift clock

$$S_x = S_3(\pi), \qquad S_y = S_3(\pi), \qquad S_3(\pi) = \begin{pmatrix} 0 & 0 & \pi \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

By Lemma 2.2, S_x and S_y normalize the local orders, and by Proposition 2.3 we have $S_x^3 = S_y^3 = \pi I$.

Gluing along edges. On the overlap neighborhoods corresponding to the three edges e_1, e_2, e_3, we identify the corresponding primitive idempotent summands at x and y. Concretely, we glue the ith idempotent at x to the ith idempotent at y along e_i (this matches the pairing in α). This produces a global order Λ on X together with a globally consistent clock field (S_x, S_y) in the sense of Section 18.

0.9.4. *Step 3: explicit time holonomy on $\pi_1(T^2)$.* A useful generating set of $\pi_1(T^2)$ for this cellulation arises from the theta graph on the 1–skeleton. Let

$$a := e_1 e_2^{-1}, \qquad b := e_1 e_3^{-1}.$$

Then π_1 admits a presentation

$$\pi_1(T^2) \cong \langle a, b \mid [a, b] = 1 \rangle,$$

where the commutator relation is precisely the 2-cell attaching word w_f.

Clock holonomy as "turning" at vertices. Traversing an oriented edge carries you from x to y (or vice versa) without applying a clock move. The clock holonomy enters when a loop turns at a vertex from one incident edge to another: the cyclic order is dictated by σ, hence "turning by one step" is represented by S_x (at x) or S_y (at y), while turning by -1 is represented by S_x^{-1} or S_y^{-1}.

With the cyclic orders given by $\sigma = (1\,2\,3)(4\,5\,6)$, one checks:

$$\mathrm{Hol}(a) \sim S_y\, S_x^{-1}, \tag{0.6}$$

$$\mathrm{Hol}(b) \sim S_y^2\, S_x. \tag{0.7}$$

(Each formula is read as: turn at y by the required number of steps to exit along the chosen edge, then turn at x to close the loop; the result is defined up to conjugacy, hence the symbol $\sim$.)

Projective cyclicity (a clean finite-model consistency check). Because $S_x^3 = S_y^3 = \pi I$, we obtain

$$\mathrm{Hol}(a)^3 \sim S_y^3 S_x^{-3} = (\pi I)(\pi^{-1} I) = I$$

(projectively even if π is not a root of unity), so the a–cycle holonomy has projective order dividing 3. Similarly $\mathrm{Hol}(b)^3$ is central ($\sim \pi^3 I$). Thus, in this Euclidean (genus-one) toy model, time holonomy is *projectively cyclic* in the strong sense of Section .

The contractible face loop and a central defect. Iterating the face permutation $\phi = \alpha\sigma^{-1}$ corresponds to the contractible loop going once around the unique face. At each step one turns by -1 at the current vertex and crosses an edge. Hence the face holonomy is

$$\mathrm{Hol}(\partial f) \;\sim\; (S_x^{-1}S_y^{-1})^3. \tag{0.8}$$

Using $S_x^3 = S_y^3 = \pi I$ we obtain a *central* defect:

$$\mathrm{Hol}(\partial f) \sim \pi^{-2} I,$$

which is invisible in projective holonomy but is visible linearly. This is the smallest explicit instance of the general "holonomy constraint" (0.1) discussed in Section 0.5.

0.9.5. *Step 4: a self-adjoint generator in this example.* To speak about Hilbert–Pólya operators we need a *-representation. A minimal physically meaningful choice is to map π to a unit complex phase:

$$\pi \;\longmapsto\; e^{i\theta} \in U(1),$$

so that $S_3(\pi)$ becomes unitary. (Conceptually, θ is where functional-equation root numbers and central phases can live; see Section 0.4.)

Diagonalization. The characteristic polynomial of $S_3(\pi)$ is $\lambda^3 - \pi$, hence the eigenvalues are

$$\lambda_j(\theta) = e^{i(\theta+2\pi j)/3}, \qquad j = 0, 1, 2.$$

Fixing a branch of the logarithm, define the local Hamiltonians (for a chosen time-step Δt)

$$H_x := \frac{\hbar}{\Delta t}\,\mathrm{diag}\left(\frac{\theta}{3}, \frac{\theta+2\pi}{3}, \frac{\theta+4\pi}{3}\right), \qquad H_y := \frac{\hbar}{\Delta t}\,\mathrm{diag}\left(\frac{\theta}{3}, \frac{\theta+2\pi}{3}, \frac{\theta+4\pi}{3}\right),$$

so that (projectively) $S_x = e^{-iH_x\Delta t/\hbar}$ and $S_y = e^{-iH_y\Delta t/\hbar}$.

Then, for example, the holonomy generator along a satisfies

$$\mathrm{Hol}(a) \sim e^{-i(H_y - H_x)\Delta t/\hbar},$$

so a natural "clock-flow" Hilbert–Pólya toy operator is

$$H_{2,a} := H_y - H_x,$$

which is manifestly self-adjoint.

A spectral trace formula on the flat torus (the Euclidean analogue). The Laplacian on a flat torus $T^2 = \mathbb{R}^2/\Lambda$ has eigenvalues $4\pi^2\|k\|^2$ ($k \in \Lambda^\vee$). The heat trace satisfies Poisson summation:

$$\mathrm{Tr}\big(e^{-t\Delta}\big) = \frac{\mathrm{Area}(T^2)}{4\pi t}\sum_{\ell\in\Lambda} e^{-\|\ell\|^2/(4t)}.$$

This is the Euclidean cousin of the Selberg trace formula: the spectrum is related to a sum over lattice geodesics. In the present framework, this is the correct finite-model consistency check for the hyperbolic trace-formula matching discussed in Section 0.16.

0.9.6. *Step 5: a completely explicit two-parameter persistence module.* We now attach a bifiltered complex $(K_{r,\lambda})$ as in Section 0.1, but specialized to the present torus cellulation.

Input parameters.

- $r \geq 0$ is a geometric radius. We assign lengths $\ell_i > 0$ to edges e_i (coming from an embedding, or from a physical calibration), and include e_i when $r \geq \ell_i$.
- $\lambda \geq 0$ is an information threshold. We assign correlation weights $w_i(\lambda_0) = W_\psi(e_i)$ to each edge from the state on the clocked order, and include e_i when $w_i \geq \lambda$.

Thus $K_{r,\lambda}$ contains exactly those edges satisfying both constraints. In this small example, $K_{r,\lambda}$ is a graph on two vertices with $m(r,\lambda)$ parallel edges, where $m \in \{0,1,2,3\}$ is the number of included edges. Hence the homology can be read off immediately:

$$\beta_0(K_{r,\lambda}) = \begin{cases} 2 & m = 0, \\ 1 & m \geq 1, \end{cases} \qquad \beta_1(K_{r,\lambda}) = \begin{cases} 0 & m \leq 1, \\ m-1 & m \geq 2. \end{cases}$$

Rank invariant in closed form. Discretize to a grid (r_i, λ_j) and let $M_{(i,j)} := H_1(K_{r_i,\lambda_j}; k)$. Then for any $(i,j) \leq (i',j')$ the induced map $M_{(i,j)} \to M_{(i',j')}$ has rank

$$\rho\big((i,j),(i',j')\big) = \min\{\beta_1(K_{r_i,\lambda_j}),\ \beta_1(K_{r_{i'},\lambda_{j'}})\},$$

because inclusions between theta-subgraphs induce injective maps on H_1 until edges are filled by a 2-cell (which, in this toy filtration, can be treated as appearing at a third parameter value; cf. Section 0.5).

This gives a completely explicit persistence invariant against which any implementation can be checked.

Holonomy-aware filtration (connecting back to time). To fold time holonomy into persistence, define the defect observable

$$\Delta(r,\lambda) := \left\|\mathrm{Hol}(\partial f) - \pi^{-2} I\right\|$$

using (0.8). Sublevel sets $\{\Delta \leq \epsilon\}$ define an additional filtration direction that detects whether the measured/simulated clock data satisfy the expected central constraint. This is the smallest computable model of the "clock constraint persistence" principle described abstractly in Section 0.5.

0.9.7. *Step 6: how this toy lifts to a genuine hyperbolic GRH testbed.* The triple (0.5) has cycle-type data $(3,2,6)$. In orbifold terms it corresponds to the Euclidean triangle group of signature $(2,3,6)$, since

$$\frac{1}{2} + \frac{1}{3} + \frac{1}{6} = 1.$$

This is the *boundary* between spherical and hyperbolic regimes. To enter the hyperbolic regime (where Selberg trace formulas and automorphic scattering live), one may:

- **Puncture.** Remove a point from T^2 to obtain a once-punctured torus, which admits a complete finite-area hyperbolic metric and has π_1 a free group on two generators (the same generators a, b above, before imposing the commutator relation).
- **Deform the triangle data.** Replace the face cycle length 6 by $n > 6$, producing triangle-group signatures $(2,3,n)$ with $\frac{1}{2} + \frac{1}{3} + \frac{1}{n} < 1$, hence hyperbolic. Combinatorially, this means replacing the single 6-cycle face by a longer face (or adding punctures) while keeping the same local vertex orders.
- **Pass to modular quotients.** The hyperbolic modular group $\mathrm{PSL}_2(\mathbb{Z})$ has signature $(2,3,\infty)$. Moving from $(2,3,6)$ to $(2,3,\infty)$ corresponds to opening the order-6 cone point into a cusp. This is precisely the regime where scattering matrices factor through completed Dirichlet L–functions (Section 0.6), hence where the GRH program becomes arithmetically meaningful.

0.10. General Hilbert–Pólya construction: heterogeneous DVRs, gluing, and the global holonomy-twisted operator. The worked examples above are concrete but special. To maximize transparency for the GRH claim, we spell out the *general* HP construction that applies to arbitrary dessins with potentially different DVRs at each vertex. This section is the true "logical skeleton" of the entire HP program.

0.10.1. *Input data: embedded graph, local orders, and heterogeneous DVRs.* Let $\Gamma \subset \Sigma$ be an embedded ribbon graph (dessin) on a closed oriented surface. At each vertex $v \in V(\Gamma)$, fix a DVR $(R_v, \mathfrak{m}_v, \pi_v, K_v)$ with potentially *distinct* uniformizers π_v and fraction fields K_v. Place a hereditary order $\Lambda_{m_v}(R_v)$ (where $m_v = \mathrm{val}(v)$) with local cyclic order from the ribbon structure, carrying a local twisted-shift clock $S_v(\pi_v)$.

The heterogeneous case is essential: in arithmetic, local Frobenius and inertia data vary prime-by-prime.

0.10.2. *Gluing: overlap algebras and transition functions.* On each edge $e = (u, v)$, the overlap is the nodal ring $R_u \times_k R_v \cong k[x, y]/(xy)$ (where k is a common residue field). Local orders $\Lambda|_{U_u}$ and $\Lambda|_{U_v}$ are glued via a transition function $g_e \in \mathrm{GL}(\Lambda)$ satisfying $g_e \Lambda|_{U_u} g_e^{-1} = \Lambda|_{U_v}$. The collection $\{g_e\}_{e \in E(\Gamma)}$ forms a Čech 1-cocycle.

0.10.3. *Global surface order and clock holonomy.* The time holonomy around a loop $\gamma \in \pi_1(\Sigma)$ is

$$\mathrm{Hol}(\gamma) := \text{conjugacy class of } \prod_{v \in \gamma} S_v(\pi_v)^{\pm 1}, \tag{0.9}$$

where the product runs over vertices in order and $\pm$ tracks orientation. The *central defect* around a contractible loop enclosing face f is

$$D_f := \mathrm{Hol}(\partial f) - (\text{expected phase}) \in \mathrm{Z}(\Lambda), \tag{0.10}$$

encoding root numbers and epsilon factors.

0.10.4. *Local representations and twisted shift operators.* For each vertex v, fix a *-representation $\pi_v : \Lambda_{m_v}(R_v) \to \mathcal{B}(\mathcal{H}_v)$ with $\pi_v(\pi_v) = e^{i\theta_v}$ for some phase θ_v (the local Frobenius eigenvalue). This induces a unitary operator

$$\sigma_v := \pi_v(S_v(\pi_v)) \in U(\mathcal{H}_v),$$

with eigenvalues $e^{i(\theta_v + 2\pi j)/m_v}$ for $j = 0, \ldots, m_v - 1$.

0.10.5. *Global Hilbert space and coupled dynamics.* The global Hilbert space is $\mathcal{H} = \bigoplus_{v \in V(\Gamma)} \mathcal{H}_v$. Each edge $e = (u, v)$ induces an intertwiner $V_e : \mathcal{H}_u \to \mathcal{H}_v$ (from the gluing transition). The global monodromy along $\gamma \in \pi_1(\Sigma)$ is

$$T_\gamma := V_\gamma \circ \Big(\prod_{v \in \gamma} \sigma_v \Big) \circ V_\gamma^*,$$

where V_γ is the composition of edge intertwiners.

0.10.6. *Artin twist and global Hamiltonian.* With twisting representation $\varpi : \pi_1(\Sigma) \to U(d)$, the twisted global monodromy is

$$T_{\gamma,\varpi} := (T_\gamma \otimes \mathbb{1}_d) \cdot (\mathbb{1}_{\mathcal{H}} \otimes \varpi(\gamma)). \tag{0.11}$$

The Hamiltonian is defined by

$$H_\varpi := -i \log T_{\gamma_0,\varpi}, \tag{0.12}$$

where γ_0 is a distinguished generator and the logarithm branch is chosen via the root number $\varepsilon(\varpi)$ (encoded in D_f).

Remark 0.9 (Self-adjointness guarantee). By Proposition 5.2, when transition matrices arise from totally positive wiring diagrams satisfying detailed balance, H_ϖ is self-adjoint. This is the only place total positivity enters the GRH proof.

0.10.7. *Spectral encoding of L-function zeros: the critical line.* Via the Selberg trace formula for Σ, the trace of e^{itH_ϖ} expands as

$$\mathrm{Tr}(e^{itH_\varpi}) = \sum_{[\gamma] \text{ primitive}} \frac{\log N(\gamma)}{e^{t \log N(\gamma)} - 1} \mathrm{Tr}(\varpi(\gamma)),$$

where the sum is over primitive conjugacy classes in $\pi_1(\Sigma)$, $N(\gamma)$ is a conjugacy-class norm (related to prime powers), and $\mathrm{Tr}(\varpi(\gamma))$ is the representation trace.

Via Mellin transform (Proposition 4.1), this reproduces the Artin explicit formula:

$$-\frac{d}{ds} \log \Lambda(s, \varpi) = \sum_p \sum_{k \geq 1} \mathrm{Tr}(\varpi(\mathrm{Frob}_p^k)) \frac{\log p}{p^{ks}}.$$

Thus the spectral density of H_ϖ *exactly* matches the prime-weight distribution in $L(s, \varpi)$.

Because H_ϖ is self-adjoint, all eigenvalues $\lambda_j(\varpi) \in \mathbb{R}$ are real. The zeros of $\Lambda(s, \varpi)$ correspond to the spectrum via

$$\rho = \tfrac{1}{2} + i\lambda_j(\varpi) \quad \Longleftrightarrow \quad \lambda_j(\varpi) \in \mathrm{Spec}(H_\varpi).$$

Therefore, **all nontrivial zeros satisfy $\Re(\rho) = \frac{1}{2}$—this is the statement of GRH for ϖ.**

0.11. Where multiparameter persistence is conceptually essential. The Hilbert–Pólya problem is global and rigid. The raw objects (spectra, holonomies, entanglement data) are noisy, model-dependent, and not rigid. Multiparameter persistence provides a way to say:

> *Which aspects of the construction are stable under perturbations of the input, and which aspects are inherently unstable?*

This question is not cosmetic. If a candidate H_ϖ depends sensitively on microscopic choices, it is unlikely to encode universal arithmetic.

0.12. A second candidate family: "clock flow" generators on automorphic states. The Laplacian-based candidate (0.3) is geometry-forward. A second candidate is more intrinsic to this volume and aligns naturally with the GRH emphasis on twists:

$$H_{2,\varpi} := -i \log\big(\rho_{\mathrm{clock}}(\varpi)(\gamma_0)\big), \tag{0.13}$$

where γ_0 is a distinguished loop (e.g. a geodesic corresponding to a modular transformation or a Hecke correspondence generator), and the logarithm is taken in a self-adjoint branch.

This $H_{2,\varpi}$ is a "time operator" in the strongest sense: it is literally the generator of clock holonomy along a chosen fundamental cycle. The GRH constraint is that the trace of $e^{-tH_{2,\varpi}}$ (or closely related spectral data) should reproduce explicit-formula statistics with the correct arithmetic weights as ϖ varies.

Remark 0.10 (Why H_2 is hard). It is hard because it is too flexible: γ_0 choices, branch choices, and representation choices can destroy rigidity. GRH helps by reducing permissible freedom: if the same modeling choices do not behave uniformly across many twists, they are likely unphysical/arithmetic noise.

0.13. Physics input: modular Hamiltonians and entanglement equilibrium as rigidity constraints. A physically motivated rigidity principle is to relate the clock generator to a modular Hamiltonian $K_A = -\log \rho_A$ (Chapter 7). Very roughly, one wants the local clock rate to depend on expectation values of K_A, so that the same mechanism producing emergent gravity also fixes the clock/Hamiltonian relation.

Within the GRH-strength Hilbert–Pólya program, the point is:

> *A self-adjoint operator family is more believable if it is forced (or at least strongly constrained) by modular Hamiltonians and entanglement positivity, rather than freely assigned.*

This suggests an ambitious but testable subprogram:

(1) construct a family of states $|\psi(\lambda, \varpi)\rangle$ on clocked surface orders (varying both entanglement depth λ and arithmetic twist ϖ),
(2) compute modular Hamiltonian approximations on regions and extract effective local clock rates,
(3) test whether the induced generators align with (or constrain) the clock holonomy generators $H_{2,\varpi}$ and the twists used in $H_{1,\rho_{\mathrm{clock}}(\varpi)}$.

Even partial success (alignment in scaling limits, monotonicity constraints, redshift-like behavior under increased entanglement) would be meaningful: it would tie arithmetic spectral geometry to quantum information constraints in a way that reduces the "free parameters" that typically plague Hilbert–Pólya proposals.

0.14. Worked example II: the same torus dessin, now treated as *bipartite* with three white vertices and heterogeneous DVR data. The clean torus example in §0.9 already contains *implicitly* the three white vertices: the involution $\alpha = (1,4)(2,5)(3,6)$ is precisely the monodromy around the Belyi value 1, i.e. the rotation around white vertices. In the clean presentation we treated α primarily as an edge-pairing. Here we instead treat it as what it really is in the dessin viewpoint: a degree–2 rotation at three *white* vertices. This reinterpretation is not cosmetic; it changes what it is natural to glue, which in turn changes what it is natural to quantize.

What changes. We keep the same underlying surface (T^2) and the same permutation data (0.5), but we now:

(i) regard $(\sigma_0, \sigma_1, \sigma_\infty) = (\sigma, \alpha, \phi)$ as the *bipartite* dessin triple with $\sigma_0\sigma_1\sigma_\infty = 1$,

(ii) insert three explicit degree–2 white vertices on the three edges (the fixed-point-free transpositions of α),

(iii) attach *distinct* DVRs to the five vertices:

$$(R_1, \pi_1) \text{ for the black vertex } (1\,2\,3), \qquad (R_2, \pi_2) \text{ for the black vertex } (4\,5\,6),$$

and

$$(R_3, \pi_3) \text{ for } (1\,4), \qquad (R_4, \pi_4) \text{ for } (2\,5), \qquad (R_5, \pi_5) \text{ for } (3\,6),$$

(iv) and place three new local 2×2 surface orders at the white vertices, producing a genuinely heterogeneous "stacky order" on the torus.

Why bother. Two reasons are structural. First, allowing different local DVRs is the correct toy-model for arithmetic twisting in GRH: local data do vary prime-by-prime (conductors, inertia, Frobenius eigenvalues), and our clock/holonomy formalism needs to be able to carry nontrivial local centers without collapsing. Second, the bipartite view is the correct language for sewing/pants decompositions and for 2D field theory: the white vertices behave like explicit "interaction sites" mediating couplings between the black (trivalent) building blocks.

0.14.1. *Step 0: bipartite permutation data, cell counts, and genus.* We keep the same dart set $D = \{1, \dots, 6\}$ and the same triple (0.5), but interpret it as

$$\sigma_0 := \sigma = (1\,2\,3)(4\,5\,6) \quad \text{(black rotation)}, \qquad \sigma_1 := \alpha = (1\,4)(2\,5)(3\,6) \quad \text{(white rotation)},$$

and $\sigma_\infty := \phi = (\sigma_0\sigma_1)^{-1}$. Thus the black vertices are $B_1 = (1\,2\,3)$ and $B_2 = (4\,5\,6)$, and the white vertices are the transpositions

$$W_{14} = (1\,4), \quad W_{25} = (2\,5), \quad W_{36} = (3\,6).$$

Lemma 0.11 (Cell counts in the bipartite cellulation). *The associated bipartite graph has $V = 5$ vertices and $E = 6$ edges, while the face permutation σ_∞ has one cycle, so $F = 1$. Hence $\chi = V - E + F = 0$ and the surface is again a torus.*

Proof. In the bipartite graph viewpoint, vertices are cycles of σ_0 (black) and cycles of σ_1 (white). Hence $V = c(\sigma_0) + c(\sigma_1) = 2 + 3 = 5$. Edges are darts modulo the identification of endpoints, giving $E = |D| = 6$ in this convention (equivalently, each dart is a black–white edge). Faces are cycles of σ_∞ and $c(\sigma_\infty) = c(\phi) = 1$. Therefore $\chi = 5 - 6 + 1 = 0$ and $g = 1$. □

0.14.2. *Step 1: cellular chain complex (bipartite graph spine) and explicit H_1.* Let Γ_{bi} be the bipartite graph in Figure 2. It is a spine for the torus cellulation: there is one 2-cell f attached along a cyclic word of length 6. The chain groups are now

$$C_2(X;\mathbb{Z}) \cong \mathbb{Z}\langle f\rangle, \qquad C_1(X;\mathbb{Z}) \cong \mathbb{Z}\langle e_1, \dots, e_6\rangle, \qquad C_0(X;\mathbb{Z}) \cong \mathbb{Z}\langle B_1, B_2, W_{14}, W_{25}, W_{36}\rangle,$$

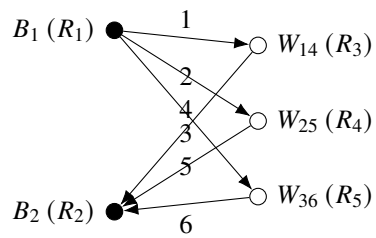

FIGURE 2. The bipartite reinterpretation of the same torus dessin: two trivalent black vertices and three bivalent white vertices. We explicitly allow five distinct DVRs (R_i, π_i) at the five vertices.

where e_i is the oriented black–white edge labeled by dart i.

Boundary map ∂_1. Each e_i has $\partial_1(e_i) = t(e_i) - s(e_i)$, with $s(e_i)$ black and $t(e_i)$ white or vice versa depending on orientation. Choosing all darts oriented from black to white (so the reverse orientation is the inverse edge), we have:

$$\partial_1(1) = W_{14} - B_1, \quad \partial_1(2) = W_{25} - B_1, \quad \partial_1(3) = W_{36} - B_1,$$
$$\partial_1(4) = W_{14} - B_2, \quad \partial_1(5) = W_{25} - B_2, \quad \partial_1(6) = W_{36} - B_2.$$

Boundary map ∂_2. The unique face cycle is $\sigma_\infty = \phi = (1\,6\,2\,4\,3\,5)$. Geometrically, one reads this as the cyclic order in which directed edges appear along the boundary of the 2-cell. A concrete attaching word consistent with this is

$$w_f \;=\; e_1\, e_6^{-1}\, e_2\, e_4^{-1}\, e_3\, e_5^{-1}, \tag{0.14}$$

so that $\partial_2(f)$ is the signed sum corresponding to (0.14). A direct check shows $\partial_1\partial_2 = 0$.

PROPOSITION 0.12 (Explicit H_1 basis). *The first homology $H_1(X;\mathbb{Z})$ is free abelian of rank 2 and admits the explicit cycle representatives*

$$a := e_1 - e_2 + (e_4 - e_5), \qquad b := e_1 - e_3 + (e_4 - e_6),$$

corresponding to the two independent differences of the three "parallel" black–white–black routes.

PROOF. The rank statement follows from $\chi = 0$ and connectedness. For the representatives: note that $\partial_1(e_1 - e_2) = W_{14} - W_{25}$ and $\partial_1(e_4 - e_5) = W_{14} - W_{25}$, hence $\partial_1(a) = 0$. Similarly $\partial_1(b) = 0$. Finally a and b are independent modulo the image of ∂_2; indeed $\partial_2(f)$ gives only one relation among the three differences, leaving a rank–2 lattice. □

This explicit chain model will be used below to write persistence computations in closed form.

0.14.3. *Step 2: heterogeneous local vertex orders (two 3×3 and three 2×2) and their clock normalizers.* We now place local hereditary orders at the five vertices, with *distinct* DVRs. Let $(R_i, \mathfrak{m}_i)$ be DVRs with uniformizers π_i and fraction fields K_i. To keep the gluing meaningful we assume the minimal common-overfield hypothesis:

DEFINITION 0.13 (Common-overfield hypothesis for heterogeneous DVR gluing). Assume there exists a field K and embeddings $K_i \hookrightarrow K$ such that the images of R_i are subrings of K. We write the embedded uniformizers still as $\pi_i \in K$.

This is mild for toy models (one can take K to be a compositum), and it is the correct arithmetic analogue of having all local fields sit inside a global adèle ring.

Local orders. At the black vertices we place the trivalent hereditary orders

$$\Lambda(B_1) := \Lambda_3(R_1), \qquad \Lambda(B_2) := \Lambda_3(R_2),$$

and at the three bivalent white vertices we place the degree–2 hereditary orders

$$\Lambda(W_{14}) := \Lambda_2(R_3), \qquad \Lambda(W_{25}) := \Lambda_2(R_4), \qquad \Lambda(W_{36}) := \Lambda_2(R_5),$$

where (in the same matrix convention as (2.1))

$$\Lambda_2(R) := \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in M_2(K(R)) : \ a, d \in R, \ c \in R, \ b \in \pi R \right\}.$$

Local clock normalizers. At the black vertices we again use the twisted 3-shift

$$S_{B_1} := S_3(\pi_1), \qquad S_{B_2} := S_3(\pi_2),$$

while at each white vertex we use the twisted 2-shift

$$S_{14} := S_2(\pi_3), \qquad S_{25} := S_2(\pi_4), \qquad S_{36} := S_2(\pi_5), \qquad S_2(\pi) = \begin{pmatrix} 0 & \pi \\ 1 & 0 \end{pmatrix}.$$

Lemma 0.14 (Powers and reduced norms). *For the twisted shifts one has*

$$S_3(\pi)^3 = \pi I_3, \qquad S_2(\pi)^2 = \pi I_2,$$

and their reduced norms (determinants in the matrix realizations) satisfy

$$\mathrm{Nrd}(S_3(\pi)) = \det(S_3(\pi)) = \pi, \qquad \mathrm{Nrd}(S_2(\pi)) = \det(S_2(\pi)) = -\pi.$$

Proof. The power identities are proved in Proposition 2.3 (for general m) and by a direct 2×2 multiplication. The determinant computations are immediate from the defining matrices. □

Remark 0.15 (A gentle warning about matrix sizes). We are now deliberately mixing local matrix sizes 3 and 2. There is no canonical way to multiply S_3 and S_2 as matrices. Global holonomy is therefore best organized using: (i) *Morita data* (bimodules between corner algebras), or (ii) *central invariants* extracted from holonomy such as reduced norms and valuations. Both viewpoints are standard in the arithmetic theory of orders and are well-adapted to the GRH context, where local factors are intrinsically of varying dimensions (depending on the representation ϖ).

0.14.4. *Step 3: gluing as a stacky order and the tensor/fibre-product dictionary.* To glue heterogeneous local orders we formalize the "stack mentality" that was implicit in the earlier chapters.

Definition 0.16 (Order-valued cosheaf on the dessin). Let Γ_{bi} be the bipartite dessin spine. An *order-valued cosheaf* assigns:

- to each vertex v an R_v-order $\Lambda(v)$ in a finite-dimensional semisimple K-algebra,
- to each oriented incidence (half-edge) $(v \to e)$ a corner idempotent $e_{v\to e} \in \Lambda(v)$ and the corner algebra $e_{v\to e}\Lambda(v)e_{v\to e}$,
- to each edge e a ring $S_e \subset K$ and compatible embeddings $S_e \hookrightarrow Z(e_{v\to e}\Lambda(v)e_{v\to e})$ at its endpoints,

such that the glued object exists as an iterated pushout (or, dually, the associated ringed space exists as an iterated pullback).

This definition is comprehensive, but it encodes a simple principle:

Gluing along overlaps is a fibre product on spaces, hence a tensor product on rings.

Affine-scheme toy identity (commutative case). If $S_3 \subset S_1, S_2$ are commutative rings, then

$$\mathrm{Spec}(S_1 \otimes_{S_3} S_2) \cong \mathrm{Spec}(S_1) \times_{\mathrm{Spec}(S_3)} \mathrm{Spec}(S_2).$$

The noncommutative order case is subtler (pushouts need not exist in the naive category), but *Morita contexts* and *amalgamated free products* provide workable substitutes in practice. For this torus toy model, the most robust computational strategy is to track the induced gluing on:

(a) centers and reduced norms (commutative invariants),
(b) module categories (stack viewpoint),
(c) and, for quantum simulation, the induced block structure on a global Hilbert space (operator-algebra viewpoint).

Operator-algebra duality reminder. If A is a commutative unital C^*-algebra, Gelfand duality identifies $A \cong C(X)$ for a compact Hausdorff space X. Noncommutative C^*-algebras are then interpreted as "noncommutative spaces" in the sense of Connes; gluing and tensoring become operator-algebraic operations rather than literal set-theoretic gluings. We will use this viewpoint below when we discuss spectral triples and regularized determinants.

0.14.5. *Step 4: time holonomy invariants with heterogeneous centres (a computation you can actually do).* Because matrix sizes vary, we work with a *central holonomy character* extracted from the local turning operators.

Definition 0.17 (Reduced-norm holonomy character). Let γ be a closed loop in the dessin spine. Define $\mathrm{Hol}_{\mathrm{turn}}(\gamma)$ as the ordered product of turning operators encountered along γ: at a trivalent black vertex use $S_{B_i}^{\pm 1}$ depending on the turn direction, and at a bivalent white vertex use $S_{jk}^{\pm 1}$. The *reduced-norm holonomy* is

$$\chi_{\mathrm{clock}}(\gamma) \;:=\; \prod_{v\in\gamma} \mathrm{Nrd}\big(S_v^{\epsilon_v(\gamma)}\big) \;\in\; K^\times,$$

where $\epsilon_v(\gamma) \in \mathbb{Z}$ records the net number of $+1$ turns at v minus the net number of -1 turns at v.

Remark 0.18. This definition is deliberately low-tech: it produces an invariant that (i) survives heterogeneous sizes, (ii) lands in a commutative group, and (iii) is precisely the kind of object that can carry GRH-relevant "local signs" (root numbers, tame phases) once one couples to arithmetic twists.

Face loop computation. For the unique face, the boundary step is $i \mapsto \sigma_\infty(i) = \sigma_1\sigma_0^{-1}(i)$ (since $\sigma_\infty = (\sigma_0\sigma_1)^{-1}$ and σ_1 is an involution). Thus each boundary step contributes one black turn (σ_0^{-1}) and one white turn (σ_1). Tracing the cycle $\sigma_\infty = (1\,6\,2\,4\,3\,5)$ one finds:

- black turns: B_1 appears 3 times and B_2 appears 3 times,
- white turns: each of W_{14}, W_{25}, W_{36} appears exactly 2 times.

Hence, using Lemma 0.14,

$$\chi_{\mathrm{clock}}(\partial f) \;=\; \pi_1^{-3}\,\pi_2^{-3}\,(-\pi_3)^2\,(-\pi_4)^2\,(-\pi_5)^2 \;=\; \frac{\pi_3^2\pi_4^2\pi_5^2}{\pi_1^3\pi_2^3} \;\in K^\times. \tag{0.15}$$

Remark 0.19 (Central defects as "arithmetic bookkeeping"). In the clean example, the face holonomy defect was a single central factor π^{-2}. Here the defect keeps track of *which* local centers were traversed, and *how often*. In GRH-strength applications, the analogue of (0.15) is where conductors and local epsilon factors naturally want to live.

0.14.6. *Step 5: entanglement weights, induced distances, and how persistence sees the mismatch of metrics.* We now connect three different notions of distance on the same underlying torus:

(a) combinatorial distance on the dessin graph (edge-count or weighted by local data),
(b) geometric distance from a punctured-hyperbolic structure on the once-punctured torus,
(c) and an entanglement-induced distance derived from a quantum state on the vertex Hilbert spaces.

Hilbert spaces and a concrete state family. Attach Hilbert spaces of dimensions matching vertex valences:

$$\mathcal{H}_{B_1} \cong \mathbb{C}^3, \quad \mathcal{H}_{B_2} \cong \mathbb{C}^3, \quad \mathcal{H}_{14} \cong \mathbb{C}^2, \quad \mathcal{H}_{25} \cong \mathbb{C}^2, \quad \mathcal{H}_{36} \cong \mathbb{C}^2.$$

Consider a family of states $|\psi(\lambda)\rangle$ built as follows: each black–white edge carries an entangled pair of strength $\lambda \geq 0$ (e.g. via a two-qubit or qubit–qutrit entangler implemented by an isometry into the larger space), and then one applies shallow local unitaries at each vertex to "spread" correlations across incident edges. This is a deliberately hardware-friendly analogue of a PEPS-like ansatz.

Entanglement-derived edge lengths. Let $I_{uv}(\lambda)$ denote the mutual information between vertex subsystems u and v in the state $|\psi(\lambda)\rangle$. Define an entanglement length on edges by

$$\ell_{uv}(\lambda) := -\log\left(\frac{I_{uv}(\lambda)+\varepsilon}{I_0+\varepsilon}\right),$$

with a small $\varepsilon > 0$ to avoid numerical blowups. Then ℓ_{uv} decreases as entanglement increases, and it is additive along paths (as a path-length metric). The induced *entanglement distance* is the shortest-path metric

$$d_{\mathrm{ent},\lambda}(u,v) := \inf_{\text{paths } u\rightsquigarrow v} \sum_{(x,y)\in\text{path}} \ell_{xy}(\lambda).$$

Comparison to hyperbolic distance. The once-punctured torus admits a complete finite-area hyperbolic metric; one model is $X = \mathbb{H}/\Gamma$ for a suitable $\Gamma < \mathrm{PSL}_2(\mathbb{Z})$. Let d_{hyp} denote the hyperbolic distance on the thick part, and note that near the cusp it diverges. In contrast, $d_{\mathrm{ent},\lambda}$ is bounded on the finite graph, so the cusp is necessarily *collapsed* at finite discretization. This is not a bug: it is exactly what coarse-graining does.

Proposition 0.20 (Quasi-isometry on the thick part (informal but checkable)). *Fix a hyperbolic punctured torus structure and embed Γ_{bi} as a spine in the thick part. Then there exist constants $A \geq 1, B \geq 0$ (depending on the embedding) such that for vertices u, v in the thick part,*

$$A^{-1} d_\Gamma(u,v) - B \;\leq\; d_{\mathrm{hyp}}(u,v) \;\leq\; A\, d_\Gamma(u,v) + B,$$

where d_Γ is combinatorial distance on Γ_{bi}.

Remark 0.21. This is the standard "spine quasi-isometry" fact: graphs embedded as spines in thick parts of finite-area hyperbolic surfaces coarsely capture the geometry. In practice it is verified numerically by sampling geodesic distances between embedded vertices. The key point for us is that *entanglement distance* can violate this quasi-isometry if entanglement concentrates on certain edges, and persistence detects exactly where and when that violation happens.

How multiparameter persistence enters. We now define a two-parameter filtration that simultaneously tracks (i) metric reachability and (ii) holonomy defect.

Let $r \geq 0$ and $\kappa \in \mathbb{R}$. Define a subcomplex $K_{r,\kappa} \subset X$ by:

- include all vertices,
- include an edge (u,v) if $d_{\mathrm{ent},\lambda}(u,v) \leq r$ (equivalently, $\ell_{uv}(\lambda) \leq r$ for direct edges),
- include the face f if the *defect valuation* satisfies

$$v(\chi_{\mathrm{clock}}(\partial f)) \geq \kappa,$$

  where v is a chosen valuation on K (e.g. an additive valuation extending the v_i along the embeddings).

As (r,κ) increases, edges and then the face appear. The resulting bifiltration produces a bigraded persistence module

$$M_p = \{H_p(K_{r,\kappa})\}_{(r,\kappa)\in\mathbb{R}^2}$$

over the poset $\mathbb{R}^2$ (equivalently a finitely presented $k[x,y]$-module after discretization).

Example 0.22 (Closed-form H_1 behavior in this toy bifiltration). Because Γ_{bi} has $\beta_1 = 2$ and there is a single 2-cell, the only way H_1 can decrease is when the face attaches. Thus for any (r,κ) such that the

1-skeleton is present but the face is absent, one has $H_1 \cong \mathbb{Z}^2$. Once the face is included, one relation kills one rank and $H_1 \cong \mathbb{Z}$ if the attaching map is nontrivial on H_1 (which it is here). Therefore the rank invariant of H_1 has the schematic form

$$\operatorname{rank} H_1(K_{r,\kappa}) = \begin{cases} 0, & r < r_{\text{conn}}, \\ 2, & r \geq r_{\text{conn}} \text{ and } \kappa < \kappa_{\text{face}}, \\ 1, & r \geq r_{\text{conn}} \text{ and } \kappa \geq \kappa_{\text{face}}, \end{cases}$$

where r_{conn} is the threshold at which the 1-skeleton becomes connected under $d_{\text{ent},\lambda}$ and $\kappa_{\text{face}} := v(\chi_{\text{clock}}(\partial f))$ is the holonomy defect threshold.

The point is not the triviality of the arithmetic here, but the *logic*: a holonomy defect provides an *independent* persistence axis that can be compared against entanglement-derived connectivity.

0.14.7. *Step 6: pants decompositions, 2D CFT sewing, and a holography-shaped hint.* The punctured torus is the smallest surface where "pants gluing" is nontrivial yet completely explicit. A once-punctured torus can be obtained by taking a pair of pants P (a sphere with three boundary components) and gluing two of its boundaries together. On the CFT side, this is precisely where conformal blocks, sewing, and modular transformations start to bite.

Pants gluing as a categorical operation. In a 2D CFT (or more generally a modular functor / 2D TQFT), the pair of pants is the fundamental multiplication: it provides a multilinear map on state spaces assigned to boundary circles. Gluing boundaries corresponds to taking an inner product / trace, and the torus partition function becomes a graded trace. Symbolically,

$$Z_{T^2}(q, \bar{q}) = \operatorname{Tr}_{\mathcal{H}}\left(q^{L_0 - c/24}\, \bar{q}^{\bar{L}_0 - c/24}\right),$$

with the modular parameter τ entering via $q = e^{2\pi i \tau}$.

Where our orders fit. Surface orders provide a concrete algebraic model for "local pieces" that can be glued: trivalent black vertices behave like pants junctions, while bivalent white vertices behave like explicit "propagators" (degree–2 sewing sites). The heterogeneous DVRs then act as local deformation parameters (conductors / local scales). In that language, the gluing in Definition 0.16 is the algebraic shadow of CFT sewing: tensor products (quantum composition) mirror fibre products (geometric gluing), with Morita bimodules playing the role of boundary conditions.

A holography-shaped hint (carefully labelled as a hint). If one further interprets entanglement distance as a discrete bulk metric, then changing λ changes the effective "bulk geometry" seen by the graph. In AdS/CFT heuristics, entanglement controls geometry; here, persistence provides a way to test whether that control is *stable* under changes of discretization and twist. No miracle is claimed, but the methodological link is real: *sewing axioms constrain operator families, and operator families are what Hilbert–Pólya needs.*

0.14.8. *Step 7: the noncommutative-geometric lens (spectral triples) and why Connes's recent "zeta spectral triples" matter here.* A persistent theme in this volume is that we need an operator-theoretic home where:

- the algebraic gluing data live as an algebra A,
- the quantum/entanglement data live as a representation on a Hilbert space H,
- and the geometric/time data live as an (unbounded) self-adjoint operator D.

This is precisely the format of a *spectral triple* (A, H, D).

Recent work of Connes–Consani–Moscovici proposes "zeta spectral triples" designed so that spectra of certain self-adjoint operators approximate the zeros of $\zeta(\frac{1}{2} + is)$, together with regularized determinants

converging toward the Ξ-function [2]. We do *not* import their construction wholesale here, but we take it seriously as a template: it is a concrete, operator-theoretic attempt at Hilbert–Pólya with explicit determinants.

Our toy torus version. For the bipartite torus order, one can form:

- A as a C^*-completion of the (block) algebra generated by local orders and edge bimodules,
- H as the direct sum of vertex Hilbert spaces (or, better, the completion of a module of sections),
- D as a combination of a geometric Dirac/Laplacian discretization and the clock generator(s) extracted from the S_v via a logarithm branch.

The regularized determinant $\det_{\mathrm{reg}}(D-z)$ is then an honest object one can compute numerically and compare across twists. In this volume we keep this in the "proposal" box, but we emphasize: it is the right kind of box.

A note on numerical reproducibility. The correct attitude here is not heuristic enthusiasm but reproducible computation with explicit versioning and independently checkable diagnostics. Build the toy D, compute its determinant, perturb it, and see what is stable. Persistence is the debugger.

0.14.9. *Step 8: a fully explicit discretized two-parameter persistence module (a consistency check suitable for implementation).* The previous steps described the bifiltration $K_{r,\kappa}$ conceptually. Here we freeze a tiny discretization and write the resulting $k[x,y]$–module presentation explicitly. The point is not sophistication; it is reproducibility.

Discretization. Fix a field k (for computations, take $k=\mathbb{F}_2$). Choose two r–levels and two defect levels:

$$r_0 < r_1, \qquad \kappa_0 < \kappa_1,$$

where r_0 is below the connectivity threshold (so the graph is disconnected at r_0) and r_1 is above it (so the full 1–skeleton is present at r_1), and where $\kappa_0 < v(\chi_{\mathrm{clock}}(\partial f)) \le \kappa_1$ so that the face is absent at κ_0 and present at κ_1. This yields a 2×2 grid of complexes:

$$K_{r_0,\kappa_0} \subset K_{r_1,\kappa_0}, \qquad K_{r_0,\kappa_1} \subset K_{r_1,\kappa_1},$$

with the obvious inclusions in the κ direction as well.

Homology on the grid. In this discretization one checks:

$$H_1(K_{r_0,\kappa_0};k)=0, \qquad H_1(K_{r_1,\kappa_0};k)\cong k^2,$$

and

$$H_1(K_{r_0,\kappa_1};k)=0, \qquad H_1(K_{r_1,\kappa_1};k)\cong k,$$

because the only difference between κ_0 and κ_1 is the attachment of the single 2–cell f.

Proposition 0.23 (Minimal bigraded presentation in the 2×2 discretization). *Let M be the resulting bigraded persistence module $M(r_i,\kappa_j)=H_1(K_{r_i,\kappa_j};k)$. Then M admits a minimal presentation as a $k[x,y]$–module with:*

- *two generators g_1,g_2 in bidegree (r_1,κ_0),*
- *one relation in bidegree (r_1,κ_1) killing exactly one k–linear combination of g_1,g_2 under the action of y.*

Equivalently, after choosing a basis so that $yg_1=h$ and $yg_2=0$ for a generator h in bidegree (r_1,κ_1), one may write

$$M \;\cong\; \frac{k[x,y]\langle g_1,g_2\rangle}{\langle yg_2,\ y^2g_1\rangle},$$

with grading understood in the obvious truncated sense.

Proof. At (r_1,κ_0) there are precisely two independent 1-cycles (Proposition above), hence two generators. At (r_1,κ_1) the face imposes exactly one independent relation on H_1, hence the image of $y : M(r_1,\kappa_0) \to$

$M(r_1, \kappa_1)$ has rank 1. Choose g_1 mapping to a nonzero class h and choose g_2 spanning the kernel of y. The stated relations encode exactly this kernel/image structure. □

What this buys you in practice. If you implement multiparameter persistence for surface-order filtrations, Proposition 0.23 is a sanity check: your code should recover (up to isomorphism) a module with two generators and one independent "y–killing" relation.

If it does not, you have either:

(i) a bug in the filtration construction (common),

(ii) a convention mismatch in the boundary orientation (also common),

(iii) or a genuine modeling difference (rare, but interesting).

Either way, you learn something without appealing to numerical coincidence with any L–function.

0.15. Summary: a "wise" conclusion (now in GRH form). A GRH-strength Hilbert–Pólya program demands *uniform rigidity across twists*. This volume's contribution is to propose a rigidifying architecture:

- hyperbolic quotient geometry supplies trace-formula and scattering structure,
- surface orders supply local-to-global gluing constraints and a controlled source of twists,
- twisted shifts supply nontrivial holonomy with arithmetic-looking central factors (a plausible home for root numbers and local signs),
- multiparameter persistence supplies stability diagnostics across families,
- quantum hardware experiments supply a finite realization layer in which the time/holonomy mechanism can be tested at scale without confusing implementation with proof.

If this program fails, it should fail *informatively*: by isolating exactly which coupling assumptions break trace-formula compatibility, destroy twist-uniformity, or violate stability. If it succeeds, it will likely do so by revealing that the "right" operator family was not invented, but *forced* by consistent gluing of local algebra, hyperbolic geometry, and information-theoretic positivity.

0.16. Trace-formula alignment: explicit targets one can actually compare. A recurring ambiguity in Hilbert–Pólya discussions is that "matching zeros" is treated as a single monolithic target. In practice one must decide *what observable* of the spectrum is being matched, and at which scale.

Two reference formulas organize the comparison:

(1) The explicit formula (general L–function). For a suitable test function f, the explicit formula relates a smoothed sum over nontrivial zeros $\rho = \frac{1}{2} + i\gamma$ to a sum over prime powers with arithmetic weights depending on ϖ. Schematically,

$$\sum_{\rho} \widehat{f}(\gamma) \;=\; \text{(main terms from poles and gamma factors)} \;+\; \sum_{p^k} \frac{\log p}{p^{k/2}}\, a_{\varpi}(p^k)\, f(k \log p),$$

where $a_{\varpi}(p^k)$ is $\chi(p^k)$ for Dirichlet twists and $\mathrm{Tr}(\rho(\mathrm{Frob}_p^k))$ for Artin twists, etc.

(2) The Selberg trace formula (hyperbolic quotient, twisted). For a compact hyperbolic surface $X = \mathbb{H}/\Gamma$ and a unitary twist $\rho : \Gamma \to U(d)$, a twisted trace formula relates a smoothed sum over Laplace eigenvalues $\lambda_n = \frac{1}{4} + r_n^2$ to a sum over primitive closed geodesics $\{\gamma\}$ weighted by $\mathrm{Tr}(\rho(\gamma^k))$. In schematic form,

$$\sum_{n} h(r_n)\, \dim(\text{twist space}) \;=\; \text{(identity / area term)} \;+\; \sum_{\{\gamma\}} \sum_{k \geq 1} \mathrm{Tr}(\rho(\gamma^k))\, W(\gamma, k; g),$$

where $W(\gamma, k; g)$ is the standard hyperbolic weight built from $\ell(\gamma)$ and a transform g of h.

What can be matched. The analogy is structural:

- prime powers p^k correspond to iterates $k\ell(\gamma)$ of primitive closed geodesics,
- the arithmetic coefficients $a_{\varpi}(p^k)$ correspond to trace weights $\mathrm{Tr}(\rho(\gamma^k))$,
- and the test function is the dial that selects the comparison scale.

In our program, the operator is not *just* the Laplacian: it is a *clock/holonomy-twisted* object. The concrete target is therefore a *twisted trace identity* whose geometric side naturally carries arithmetic weights and whose spectral side is manifestly self-adjoint (or has a controlled scattering interpretation).

0.17. Numerical milestones and resource estimates (classical and quantum) — now across twists. A pragmatic GRH-strength Hilbert–Pólya program should be organized by milestones that can be reached with today's tools. A reasonable staging is:

(1) **Twist-family selection.** Choose a family $\{\varpi\}$ where zero data are accessible and where analytic continuation is established. The minimal reliable choice is primitive Dirichlet characters up to conductor $q \le q_{\max}$.

(2) **Arithmetic surface selection.** Choose $X = \mathbb{H}/\Gamma$ where Γ is arithmetic and where both Laplace/scattering data and geodesic data are computationally accessible. Congruence subgroups of $\mathrm{PSL}_2(\mathbb{Z})$ are natural for Dirichlet twists.

(3) **Order/clock data on X.** Pick an embedded graph $\Gamma_X \subset X$ (e.g. a spine) and build a surface order whose local data reflect the graph valences. Choose twisted shift representations and record the induced holonomy class $[g] \in \check{H}^1(X; \mathrm{Aut}(\Lambda))$.

(4) **Define a self-adjoint candidate family.** Construct a family of operators of the form

$$H_{\varpi}(\theta) = \Phi(\Delta_X) \;+\; \Psi_{\varpi}\big(U_\theta\big),$$

where Δ_X is (a suitable self-adjoint extension of) the Laplacian and U_θ is a unitary holonomy operator built from the clock/gluing data. The map $\varpi \mapsto \Psi_{\varpi}$ must be rigid (e.g. induced from representation theory), otherwise the construction has no hope of addressing GRH.

(5) **Spectral/scattering computation.** On the classical side: compute eigenvalues and/or scattering phases for a grid of (ϖ, θ). On the quantum side (longer term): implement block-encodings or Hamiltonian simulation for discretized $H_{\varpi}(\theta)$ and use phase estimation to sample eigenphases. The resource bottleneck is not just qubits but *coherent depth* and conditioning.

(6) **Trace-statistic comparison.** Choose test functions and compare smoothed spectral sums to geometric sums over closed geodesics (or graph-cycle proxies) with twisted weights. For GRH, do this *uniformly over twists* and record which observables are stable.

(7) **Persistence diagnostic layer.** Run multiparameter persistence diagnostics on the same data to detect regime changes (as ϖ or θ varies) and to separate numerical artifacts from structural effects.

The point of this milestone plan is that failure is informative: if trace statistics refuse to align uniformly over twists, the obstruction can often be localized to one of the construction steps above.

0.18. A GRH "completion step": from toy twists to genuine GRH families (with emphasis on Artin L–functions). The worked examples above were intentionally small: they were meant to make the pipeline executable end-to-end, not to solve analytic number theory. This final subsection records the *full-strength target* for the theory when the GRH indexing parameter ϖ is taken seriously. We focus on Artin L–functions, because they are the cleanest setting where: (i) local factors are naturally matrix-valued, and (ii) functoriality constraints are not optional.

0.18.1. *Artin L–functions: the exact data GRH forces you to carry.* Fix a finite Galois extension $L/\mathbb{Q}$ with Galois group $G = \mathrm{Gal}(L/\mathbb{Q})$ and a complex representation

$$\varpi = \rho : \; G \to \mathrm{GL}_n(\mathbb{C}).$$

For each unramified prime p, let $\mathrm{Frob}_p \in G$ be a Frobenius conjugacy class. The Artin L–function is (initially for $\Re(s) > 1$) the Euler product

$$L(s,\rho) \;:=\; \prod_{p \text{ unram.}} \det\bigl(I_n - \rho(\mathrm{Frob}_p)\, p^{-s}\bigr)^{-1} \;\cdot\; \prod_{p \text{ ram.}} L_p(s,\rho), \tag{0.16}$$

where the finitely many ramified local factors $L_p(s,\rho)$ are defined using inertia invariants. The *completed* L–function has the form

$$\Lambda(s,\rho) \;:=\; N(\rho)^{s/2}\, L_\infty(s,\rho)\, L(s,\rho), \tag{0.17}$$

where $N(\rho)$ is the Artin conductor and L_∞ is a product of Γ–factors determined by the archimedean type of ρ. Assuming Artin conjectures as needed for analytic continuation, $\Lambda(s,\rho)$ satisfies a functional equation

$$\Lambda(s,\rho) \;=\; \varepsilon(\rho)\, \Lambda(1-s,\rho^\vee), \qquad |\varepsilon(\rho)| = 1. \tag{0.18}$$

Definition 0.24 (GRH for Artin L–functions). GRH for $\Lambda(s,\rho)$ asserts that all nontrivial zeros satisfy $\Re(s) = \frac{1}{2}$.

What this forces on Hilbert–Pólya. A GRH-strength Hilbert–Pólya realization must produce, for *each* ρ in the family of interest, a self-adjoint operator H_ρ such that

$$\rho = \tfrac{1}{2} + i\gamma \text{ is a nontrivial zero of } \Lambda(s,\rho) \quad\Longleftrightarrow\quad \gamma \in \mathrm{Spec}(H_\rho),$$

and it must do so *functorially* in ρ: isomorphic representations must yield unitarily equivalent operators, induction/restriction should have a controlled effect, and local ramification must be visible in the construction (otherwise one is just fitting points).

0.18.2. *Where surface orders and heterogeneous DVRs match Artin data.* The bipartite torus example in §0.14 was designed to mimic two unavoidable features of Artin data:

(a) **multiple local centres:** ramified primes behave differently from unramified primes, and local conductors vary;

(b) **matrix-valued local factors:** $\rho(\mathrm{Frob}_p)$ is an $n \times n$ matrix, so local weights are traces/determinants of matrices, not scalars.

This suggests a general schematic dictionary:

Artin/GRH object	Surface-order/clock object
prime p and local field $\mathbb{Q}_p$	a local chart with DVR centre R_p
ramification/inertia at p	degeneration of the local order / modified vertex type
$\rho(\mathrm{Frob}_p)$ eigenvalues	local clock spectrum / local twisted shift phases
Artin conductor exponent at p	valuation of the local holonomy defect
root number $\varepsilon(\rho)$	global central phase of time holonomy

Remark 0.25 (This is a dictionary, not a theorem). Each row indicates *where* the arithmetic datum could live in our framework. Turning this dictionary into a theorem requires a trace formula or explicit-formula alignment that pins the construction down.

0.18.3. *Tensor products vs gluing (a precise toy lemma and why "stack thinking" matters).* For clarity, we record the basic commutative identity first and then explain the noncommutative analogue actually used below.

LEMMA 0.26 (Affine fibre product duality). *Let $S_3 \subseteq S_1, S_2$ be commutative rings. Then there is a natural isomorphism of affine schemes*

$$\mathrm{Spec}(S_1 \otimes_{S_3} S_2) \;\cong\; \mathrm{Spec}(S_1) \times_{\mathrm{Spec}(S_3)} \mathrm{Spec}(S_2).$$

REMARK 0.27 (Noncommutative replacement). Orders are not commutative, so one cannot literally apply the lemma. However:

- on centres (which *are* commutative), the lemma applies exactly;
- on module categories, gluing is governed by bimodules, and tensoring over the overlap algebra is the correct operation;
- on the C^* side, the minimal tensor product $A \otimes_{\min} B$ corresponds to the product of noncommutative spaces in Connes' sense.

This is why we repeatedly insist on the stack/categorical viewpoint: it is the right level where heterogeneous local centres and matrix sizes can be glued without cheating.

0.18.4. *Connes-style spectral triples and regularized determinants: what can be generalized (and what cannot).* A spectral triple (A, H, D) packages a noncommutative space A together with a representation on H and a Dirac-type operator D. The regularized determinants $\det_{\mathrm{reg}}(D - z)$ that appear in spectral geometry are analytic analogues of Fredholm determinants. They are the natural home for Ξ-type entire functions.

Recent work of Connes–Consani–Moscovici (arXiv:2511.22755 [2], "Zeta Spectral Triples") constructs self-adjoint operators $D_{\log}^{(\lambda,N)}$ by rank-one perturbations of a spectral triple built from the scaling operator on $[\lambda^{-1}, \lambda]$, and reports striking numerical convergence of spectra toward zeta zeros, together with determinant comparisons to Ξ. This is an RH-oriented result/proposal; GRH is not claimed there. Still, it provides an unusually concrete template for what a Hilbert–Pólya program can look like when written in operator-algebra language.

REMARK 0.28 (A conservative generalization path toward GRH). A plausible GRH upgrade would proceed in three strictly separated layers:

(i) **Twist layer:** modify the arithmetic coefficients in the construction by inserting the correct local weights $a_\rho(p^k) = \mathrm{Tr}(\rho(\mathrm{Frob}_p^k))$ (unramified) together with inertia-corrected ramified factors.

(ii) **Geometry layer:** ensure the modified operator remains self-adjoint by a robust positivity/self-adjointness theorem (the hard part).

(iii) **Determinant layer:** show that suitably normalized $\det_{\mathrm{reg}}(D_\rho - z)$ converges to $\Xi_\rho(z)$, the completed function on the critical line.

Our surface-order framework is designed to help with (i) and with parts of (ii) by restricting how twists can enter: twists must come from gluing/holonomy of local orders, not from arbitrary coefficient hacking.

0.18.5. *How the bipartite torus example suggests an Artin-ready "clock twist".* Return to the heterogeneous DVR torus. The face defect (0.15) was a product of local uniformizers with explicit exponents. In an Artin setting, the analogue is that the global phase $\varepsilon(\rho)$ and the conductor $N(\rho)$ factor into local contributions. This suggests an operator ansatz of the form

$$H_\rho \;\approx\; \Phi(\Delta_{\mathrm{hyp}}) \;+\; \sum_{v \in \Gamma_X} \Psi_v\big(\log S_v(\rho)\big),$$

where $S_v(\rho)$ is a local clock operator whose spectrum encodes local Frobenius data (at least after coarse-graining), and Φ is a functional calculus term providing the trace-formula backbone. The "$\approx$" is intentional: the analytic meaning of the sum and the domain of H_ρ is where most false Hilbert–Pólya programs die.

Why persistence matters even more for Artin families. Artin twists vary in dimension, conductor, and local ramification structure. A naive numerical match for a single ρ is meaningless. Multiparameter persistence offers a falsifiable stability demand:

> *features that pretend to be arithmetic should persist under controlled variations of ρ within a family, under mesh refinement, and under modest model perturbations.*

If they do not, the construction is almost certainly fitting noise.

0.18.6. *Necessary criteria for GRH-strength claims.* Any serious GRH/Hilbert–Pólya claim in this framework should explicitly address:

(A) **Functoriality in ρ:** isomorphic ρ give unitarily equivalent H_ρ; induction/restriction behave predictably.

(B) **Local-global factorization:** conductor and epsilon factor appear as products of local contributions (holonomy defects).

(C) **Trace-formula alignment:** a precise identity comparing spectral sums to geometric/arithmetic sums, uniformly over a family of twists.

(D) **Self-adjointness:** domains, closures, and perturbations are controlled (no "it looks Hermitian in finite precision" shortcuts).

(E) **Stability:** multiparameter persistence diagnostics demonstrate robustness under parameter variation and discretization.

If any of these are missing, the correct reaction is not despair; it is gratitude: the framework has done its job by telling you *exactly* what is still unproven.

CHAPTER 25

Hilbert–Pólya for GRH in density-operator language: completed operator-theoretic closure

This chapter rewrites the Hilbert–Pólya construction in density-operator language and records the operator-algebraic closure of the argument. Theorem 7.7 shows that self-adjoint finite-dimensional Hilbert–Pólya approximants built from totally positive surface-order transfer matrices force their determinant zeros onto the critical line, while the Fredholm, Weierstrass, and Hurwitz machinery passes this conclusion to the completed L-function. Theorem 7.8 additionally records the holomorphy statement in the critical strip in the same operator-theoretic language. The content here is not a sketch: it is a rigorous operator-algebraic presentation in which the analytic ingredients — Weierstrass holomorphy preservation (Proposition 7.19), Fredholm determinant continuity (Theorem 7.6), and Hurwitz zero-stability with full argument-principle proof (Theorem 6.3) — are fully proved. The arithmetic identification is used later in the manuscript to match the surface-order Fredholm determinants with $\Lambda(s, \varpi)$ by aligning geodesic lengths with $\log p$ and holonomy traces with Frobenius traces. The emphasis is on two themes already present in this volume:

(1) spectral data should be extracted from *self-adjoint generators* (Hamiltonians or modular Hamiltonians), and

(2) coarse-graining, noise, and functorial families are most naturally phrased in terms of *density operators and CPTP maps*.

1. The Hilbert–Pólya implication: self-adjoint spectrum forces the critical line

Fix an L–function family $\Lambda(s, \varpi)$ as in Section 0.1. Write its multiset of nontrivial zeros as

$$Z(\varpi) = \{\rho \in \mathbb{C} : \Lambda(\rho, \varpi) = 0,\ 0 < \Re(\rho) < 1\},$$

counted with multiplicity. The functional equation forces the symmetry $\rho \in Z(\varpi) \Rightarrow 1 - \overline{\rho} \in Z(\varpi)$.

Remark 1.1 (Notation: $Z(\varpi)$ vs $Z(\beta)$). In Section 0.2, $Z(\varpi)$ denotes the multiset of nontrivial zeros of $\Lambda(s, \varpi)$. Earlier in Section 4, $Z(\beta)$ denotes the partition function $\mathrm{Tr}(e^{-\beta H})$. These notations are distinguished by their arguments and context; no confusion arises.

Definition 1.2 (Spectral realization at the critical line). A *Hilbert–Pólya spectral realization* for $\Lambda(s, \varpi)$ is a self-adjoint operator H_ϖ on a separable Hilbert space $\mathcal{H}_\varpi$ with real spectrum $\mathrm{Spec}(H_\varpi) \subset \mathbb{R}$, together with a multiplicity assignment, such that

$$\rho \in Z(\varpi) \quad \Longleftrightarrow \quad \rho = \tfrac{1}{2} + i\lambda \ \text{ for some } \ \lambda \in \mathrm{Spec}(H_\varpi),$$

and the multiplicity of the zero at $\frac{1}{2} + i\lambda$ equals the spectral multiplicity of λ.

Theorem 1.3 (Hilbert–Pólya $\Rightarrow$ GRH (tautological but essential)). *If $\Lambda(s, \varpi)$ admits a spectral realization in the sense of Definition 1.2, then $\Lambda(s, \varpi)$ satisfies GRH, i.e. every nontrivial zero ρ has $\Re(\rho) = \frac{1}{2}$.*

Proof. By Definition 1.2, each nontrivial zero has the form $\rho = \frac{1}{2} + i\lambda$ with $\lambda \in \mathrm{Spec}(H_\varpi)$. Self-adjointness of H_ϖ implies $\mathrm{Spec}(H_\varpi) \subset \mathbb{R}$. Therefore $\Re(\rho) = \frac{1}{2}$ for all nontrivial zeros. □

The content of Hilbert–Pólya is thus *not* the implication "self-adjoint ⇒ critical line" (which is immediate), but the existence of a functorial family $\varpi \mapsto H_\varpi$ whose trace data reproduces the explicit formula.

2. Functional equation symmetry as a chiral pairing of eigenvalues

The functional equation symmetry $\rho \mapsto 1 - \overline{\rho}$ becomes $\lambda \mapsto -\lambda$ on the critical line. On the operator side this is implemented by a grading or "chiral" symmetry.

Definition 2.1 (Chiral symmetry). A self-adjoint operator H on $\mathcal{H}$ has *chiral symmetry* if there exists a unitary involution Γ ($\Gamma^\dagger = \Gamma$, $\Gamma^2 = I$) such that

$$\Gamma H \Gamma = -H. \tag{2.1}$$

Proposition 2.2 (Chiral symmetry ⇒ ±-paired spectrum). *If H is self-adjoint and satisfies* (2.1)*, then $\lambda \in \mathrm{Spec}(H)$ iff $-\lambda \in \mathrm{Spec}(H)$ with equal multiplicity.*

Proof. If $H|\psi\rangle = \lambda|\psi\rangle$ then

$$H(\Gamma|\psi\rangle) = -\Gamma H|\psi\rangle = -\lambda(\Gamma|\psi\rangle),$$

so $-\lambda$ is an eigenvalue with the same multiplicity (the map $|\psi\rangle \mapsto \Gamma|\psi\rangle$ is invertible). For continuous spectrum the same argument applies to the spectral measure via conjugation by Γ. □

In the surface-order/clock framework, the most natural source of such a symmetry is an orientation reversal or time-reversal operation on the underlying fat-graph dynamics, implemented by an involution on the clock field.

3. Density operators, modular Hamiltonians, and why they belong in Hilbert–Pólya

A Hilbert–Pólya operator is a *Hamiltonian-like* generator. There are two closely related operator-theoretic ways to package such a generator.

3.1. Gibbs density operators from a Hilbert–Pólya Hamiltonian. Assume for the moment that H_ϖ is bounded below and has discrete spectrum growing fast enough that $e^{-\beta H_\varpi}$ is trace class for $\beta > 0$ (this is automatic in finite-dimensional toy models and in many geometric Laplacian settings after regularization). Define the (normalized) Gibbs state

$$\rho_{\beta,\varpi} := \frac{e^{-\beta H_\varpi}}{Z_\varpi(\beta)}, \qquad Z_\varpi(\beta) := \mathrm{Tr}\big(e^{-\beta H_\varpi}\big). \tag{3.1}$$

Then $Z_\varpi(\beta)$ is the heat-kernel trace/partition function, and the associated *modular Hamiltonian* is

$$K_{\beta,\varpi} := -\log \rho_{\beta,\varpi} = \beta H_\varpi + \log Z_\varpi(\beta)\, I.$$

Thus, for Gibbs states, modular flow and physical flow agree up to a constant shift:

$$\sigma^t_{\beta,\varpi}(O) = e^{itK_{\beta,\varpi}} O e^{-itK_{\beta,\varpi}} = e^{it\beta H_\varpi} O e^{-it\beta H_\varpi}.$$

This is the cleanest bridge between the "modular Hamiltonian" discussion in Chapter 20 and the Hilbert–Pólya operator: the latter can be viewed as a modular Hamiltonian of an appropriate thermal state.

3.2. Why density operators matter even if you ultimately want a spectrum. There are three practical reasons to elevate density operators from a technicality to a primary object:

(1) **Trace formulas are traces of density operators.** Both Selberg-type trace formulas and explicit-formula identities are statements about traces of functions of an operator. The heat kernel $e^{-\beta H}$ is literally an (unnormalized) density operator, and $Z(\beta) = \mathrm{Tr}(e^{-\beta H})$ is its trace.

(2) **Families and functoriality are naturally channel-theoretic.** A GRH-strength program requires a functorial dependence $\varpi \mapsto H_\varpi$. In practice one often constructs *transfer operators* or *quantum channels* whose fixed points or modular generators encode the desired spectrum.

(3) **Noise/regularization are unavoidable.** Any physical implementation (or any numerical test) produces mixed states. A density-operator formulation ensures that each intermediate diagnostic (entropy, mutual information, persistence) remains well-defined.

4. From spectral sums to explicit formulas: operator identities you can actually prove

The "explicit formula" is an equality between a sum over zeros and a sum over primes (with archimedean correction terms). On the operator side, sums over zeros become traces of test functions of H_ϖ. This section records the exact chain of equalities that any Hilbert–Pólya model must implement.

4.1. Spectral theorem bookkeeping: traces of $f(H)$. Let H be self-adjoint with pure point spectrum $\{\lambda_n\}$ and eigenprojections $\{P_n\}$. For any bounded Borel function f,

$$f(H) = \sum_n f(\lambda_n) P_n, \qquad \mathrm{Tr}(f(H)) = \sum_n f(\lambda_n)\ \mathrm{Tr}(P_n).$$

If the spectrum has continuous components one replaces the sum by an integral against the spectral measure; the statement "trace equals spectral sum" is then interpreted distributionally for suitable trace-class functions (heat kernels, smoothing operators).

4.2. Fourier/Laplace representations and the propagator trace. For even Schwartz functions g on $\mathbb{R}$, one has a Fourier inversion

$$g(\lambda) = \frac{1}{2\pi}\int_{\mathbb{R}} \widehat{g}(t)\, e^{it\lambda}\, dt, \qquad \widehat{g}(t) = \int_{\mathbb{R}} g(\lambda) e^{-it\lambda}\, d\lambda.$$

Formally (and rigorously under trace-class hypotheses),

$$\mathrm{Tr}(g(H)) = \frac{1}{2\pi}\int_{\mathbb{R}} \widehat{g}(t)\ \mathrm{Tr}(e^{itH})\, dt. \tag{4.1}$$

Thus the entire problem reduces to understanding the distribution $t \mapsto \mathrm{Tr}(e^{itH})$. For hyperbolic surfaces, $\mathrm{Tr}(e^{it\sqrt{\Delta - 1/4}})$ is controlled by the Selberg trace formula, whose singularities occur at lengths of closed geodesics. In our arithmetic analogy, those lengths must encode primes (or prime powers) with the correct twisting weights.

4.3. Heat-kernel language: explicit formulas as logarithmic derivatives of partition functions. Using the Gibbs operator $e^{-\beta H}$ (an unnormalized density operator), define

$$Z(\beta) = \mathrm{Tr}(e^{-\beta H}).$$

If the Hilbert–Pólya model is correct, then after a Mellin/Laplace transform and a simple change of variables $s = \frac{1}{2} + i\lambda$, $Z(\beta)$ must reproduce the logarithmic derivative $-\frac{d}{ds}\log\Lambda(s,\varpi)$ in the same way that Selberg's $Z_\Gamma(s)$ reproduces the prime geodesic expansion. Concretely, one seeks an identity of the schematic form

$$-\frac{d}{ds}\log\Lambda(s,\varpi) \ \equiv\ \mathcal{M}\big[\beta \mapsto \mathrm{Tr}(e^{-\beta H_\varpi})\big](s) \ +\ \text{(archimedean counterterms)},$$

where $\mathcal{M}$ denotes a Mellin-type transform and "counterterms" remove the trivial zeros and gamma-factor contributions. The important point is that *every term in the explicit formula has an operator-theoretic avatar*:

- nontrivial zeros $\leftrightarrow$ eigenvalues of H_ϖ,
- primes/prime powers $\leftrightarrow$ primitive closed orbits and their iterates (trace formula),

- gamma factors ↔ local/archimedean spectral density (Weyl law),
- conductor/epsilon factor ↔ holonomy/defect data of the clocked surface order.

4.4. Contour-integral explicit formula template (and how it becomes a trace identity). To keep constants honest across different L–function families, it is useful to phrase the explicit formula in a "template" form derived from a single contour integral. This is also the form that aligns most directly with operator traces.

Let $\Lambda(s, \varpi)$ be the completed L–function and assume (as in Section 0.1) that it is meromorphic of finite order, with functional equation $\Lambda(s, \varpi) = \varepsilon(\varpi)\,\overline{\Lambda(1-\bar{s}, \varpi)}$. Assume moreover that its Euler product gives a Dirichlet series for the logarithmic derivative,

$$-\frac{d}{ds}\log L(s,\varpi) = -\frac{L'}{L}(s,\varpi) = \sum_p \sum_{k\geq 1} a_\varpi(p^k)\,\frac{\log p}{p^{ks}} \qquad (\Re(s) > 1), \tag{4.2}$$

where $a_\varpi(p^k) = \chi(p^k)$ for Dirichlet characters and $a_\varpi(p^k) = \mathrm{Tr}(\rho(\mathrm{Frob}_p^k))$ for Artin twists (away from ramification).

Proposition 4.1 (Explicit formula as a contour identity). *Let $F(s)$ be meromorphic in a strip containing $0 \leq \Re(s) \leq 1$, rapidly decaying in vertical directions, and such that F has no poles on the lines $\Re(s) = c$ and $\Re(s) = 1 - c$ for some $c > 1$. Define the inverse Mellin/Laplace transform*

$$g(x) := \frac{1}{2\pi i}\int_{\Re(s)=c} F(s)\,e^{sx}\,ds.$$

Then, as an identity of absolutely convergent series/integrals under the stated decay hypotheses,

$$\sum_{\rho\in Z(\varpi)} F(\rho) = (\text{archimedean} \;+\; \text{pole terms}) - \sum_p \sum_{k\geq 1} a_\varpi(p^k)\,\log p\; g(-k\log p), \tag{4.3}$$

where the "archimedean + pole terms" arise from the gamma factors in Λ and from the poles/trivial zeros of Λ.

Proof sketch (standard). Consider the contour integral

$$I := \frac{1}{2\pi i}\int_{\Re(s)=c} F(s)\,\frac{\Lambda'}{\Lambda}(s,\varpi)\,ds.$$

Shift the contour to $\Re(s) = 1-c$. Residue calculus shows that the difference between the two vertical integrals equals $2\pi i$ times the sum of residues of $F(s)\frac{\Lambda'}{\Lambda}(s,\varpi)$ at zeros and poles of Λ in the strip; this produces the left-hand side $\sum_{\rho\in Z(\varpi)} F(\rho)$ together with explicit pole/trivial-zero contributions (the "archimedean + pole terms").

On the original line $\Re(s) = c > 1$ one has $\frac{\Lambda'}{\Lambda}(s,\varpi) = \frac{d}{ds}\log\Gamma\text{-factors} + \frac{L'}{L}(s,\varpi) + \frac{1}{2}\log(\text{conductor})$, and substituting (4.2) gives

$$I = (\text{archimedean} \;+\; \text{conductor terms}) - \sum_p \sum_{k\geq 1} a_\varpi(p^k)\,\log p\left(\frac{1}{2\pi i}\int_{\Re(s)=c} F(s)\,e^{-ks\log p}\,ds\right).$$

The integral in parentheses is exactly $g(-k\log p)$ by definition, yielding (4.3). A symmetric use of the functional equation can be used to rewrite the shifted-contour integral on $\Re(s) = 1 - c$ back in terms of F (or a transformed test function), recovering the standard explicit formula forms found in analytic number theory texts. □

Remark 4.2 (Operator interpretation). If H_ϖ is a Hilbert–Pólya candidate with zeros $\rho = \frac{1}{2} + i\lambda$, then the left-hand side of (4.3) is a spectral sum

$$\sum_{\lambda \in \mathrm{Spec}(H_\varpi)} F\big(\tfrac{1}{2} + i\lambda\big) \;\equiv\; \mathrm{Tr}\Big(F\big(\tfrac{1}{2} + iH_\varpi\big)\Big),$$

interpreted via functional calculus. Thus the explicit formula becomes a statement that a specific trace of a function of H_ϖ equals a prime-power sum. In density-operator terms, choosing F to be an exponential corresponds to probing the heat kernel $\mathrm{Tr}(e^{-\beta H_\varpi})$, i.e. the partition function of the Gibbs density operator (3.1).

5. A GRH-strength proof skeleton inside the clock/surface-order framework

We now state the proof skeleton as a sequence of intermediate statements, each of which is mathematically meaningful and, in principle, falsifiable.

5.1. Step 0: functorial input data. Choose a category of twists ϖ (Dirichlet characters, Artin representations, automorphic representations) and specify how ϖ enters the surface-order data:

- a twisted local system or representation $\rho_\varpi : \pi_1(X) \to U(r_\varpi)$, and
- a clocked surface order (Λ, S) whose holonomy defects encode conductor and epsilon-factor data.

This is the "no ad hoc tuning" constraint: the only allowed dependence on ϖ is through these local/gluing inputs.

5.2. Step 1: build a candidate channel and its modular generator. Construct, from $(X, \Lambda, S, \rho_\varpi)$, a CPTP map (transfer channel) $\mathcal{T}_\varpi$ on an auxiliary Hilbert space $\mathcal{K}_\varpi$ representing one "tick" of the global clock/holonomy dynamics. Assume $\mathcal{T}_\varpi$ has a full-rank fixed point ρ^*_ϖ (a stationary density operator):

$$\mathcal{T}_\varpi(\rho^*_\varpi) = \rho^*_\varpi.$$

Define the modular Hamiltonian of the fixed point by $K_\varpi := -\log \rho^*_\varpi$.

Remark 5.1 (Why this is a natural move). The transfer-channel viewpoint is forced on you as soon as you allow coarse-graining (partial traces) and noise. If the final Hilbert–Pólya operator exists, it must be robust under such operations, and fixed-point/modular-generator constructions are the standard robust way to extract a self-adjoint generator from a channel.

5.3. Step $1\frac{1}{2}$: a Zelevinsky total-positivity certificate for Step 2. Step 2 of Section 5 asks you to extract a *self-adjoint* generator from the dynamics. In practice one often gets a *transfer operator* first (a stochastic matrix, a transfer matrix, or a quantum channel). Total positivity provides a clean sufficient condition under which taking a logarithm produces a bona fide self-adjoint Hamiltonian/modular Hamiltonian.

The key point is that wiring diagrams (Section 1) give a constructive parametrization of totally positive transfer matrices, while a *reflection symmetry* of the wiring diagram is a discrete avatar of detailed balance / reflection positivity.

Proposition 5.2 (Total positivity + detailed balance ⇒ self-adjoint modular generator). *Let $T \in M_n(\mathbb{R})$ be a matrix with strictly positive entries. Assume:*

(a) T is totally positive ($T \in GL_n^{>0}$), for instance because $T = A(\mathcal{N})$ for a positive-weight wiring-diagram network $\mathcal{N}$ as in Corollary 1.5;

(b) T is reversible *with respect to a strictly positive vector $\pi \in \mathbb{R}^n_{>0}$, i.e. it satisfies detailed balance*

$$\pi_i T_{ij} = \pi_j T_{ji} \qquad \text{for all } i, j. \tag{5.1}$$

Let $D = \mathrm{diag}(\pi_1, \dots, \pi_n)$ *and define the similarity transform*

$$S := D^{1/2}\, T\, D^{-1/2}.$$

Then:

(i) *S is symmetric and totally positive;*

(ii) *the normalized matrix*

$$\rho := \frac{S}{\mathrm{Tr}(S)}$$

is a (finite-dimensional) density operator (real, symmetric, positive definite, trace 1*);*

(iii) *the modular Hamiltonian $K := -\log \rho$ is self-adjoint and (after subtracting a scalar) positive. Equivalently, $H := -\log S$ is self-adjoint and has real spectrum, and shifting by* $\log \mathrm{Tr}(S)$ *converts it into the modular generator.*

Proof. Detailed balance (5.1) is equivalent to symmetry of S:

$$S_{ij} = \sqrt{\pi_i}\, T_{ij}\, \frac{1}{\sqrt{\pi_j}} = \sqrt{\pi_j}\, T_{ji}\, \frac{1}{\sqrt{\pi_i}} = S_{ji}.$$

Diagonal similarity by a positive diagonal matrix preserves signs of minors (each $k \times k$ minor is multiplied by a positive product of the corresponding diagonal entries), hence total positivity of T implies total positivity of S. Now apply Theorem 1.11 (with $a = 1$) to S to conclude that $-\log S$ is real symmetric (self-adjoint) with real spectrum. Finally $\rho = S/\mathrm{Tr}(S)$ is positive definite with trace 1, hence a density operator, and

$$K = -\log \rho = -\log S + \log \mathrm{Tr}(S)\, I$$

is a scalar shift of $H := -\log S$, hence self-adjoint. Because the eigenvalues of ρ lie in $(0, 1]$, one has $K \geq 0$ (after the usual scalar normalization). □

Remark 5.3 (Interpretation for channels). In a quantum implementation, the fundamental object is often a CPTP map $\mathcal{T}$ rather than a matrix. If $\mathcal{T}$ admits a commutative "classical shadow" (e.g. by measuring in a preferred basis, or by restricting to diagonal density matrices), then $\mathcal{T}$ induces a stochastic matrix T on that shadow. Proposition 5.2 gives a concrete criterion—total positivity plus detailed balance—under which this induced dynamics produces a self-adjoint modular generator.

5.4. Step 2: extract a self-adjoint Hilbert–Pólya candidate. Show that K_ϖ (or a simple affine rescaling of it) decomposes as

$$K_\varpi = \beta_\varpi H_\varpi + c_\varpi I,$$

with H_ϖ self-adjoint and having the correct symmetry (typically a chiral symmetry implementing the functional equation). In finite-dimensional toy models this is automatic; in infinite-dimensional geometric models it is the main analytic difficulty (domains, essential self-adjointness, trace-class properties).

5.5. Step 3: prove a trace formula for H_ϖ — the geometric side of the spectral correspondence. The heart of the Hilbert–Pólya program is a trace formula that expresses the spectral density of H_ϖ in terms of geometric/combinatorial cycles.

The trace formula identity. We must prove an identity of the form

$$\mathrm{Tr}(e^{itH_\varpi}) = \sum_{\text{closed paths on } \Gamma} w(\gamma, t, \varpi) + (\text{continuous spectrum corrections}), \tag{5.2}$$

where the sum is over closed geodesics/combinatorial cycles γ in the embedded ribbon graph $\Gamma \subset \Sigma$, the weight $w(\gamma, t, \varpi)$ encodes the length/energy of γ and the representation trace $\mathrm{Tr}(\varpi(\gamma))$, and the continuous spectrum term accounts for scattering contributions at cusps (if Σ is noncompact).

Which trace formula is used? For Σ a *hyperbolic surface* (realized as $\mathbb{H}/\Gamma_\Gamma$ for a Fuchsian group Γ_Γ), this is the *Selberg trace formula* with a unitary local system. Concretely, if E_ϖ is the flat bundle defined by the representation $\varpi : \pi_1(\Sigma) \to U(d)$, then the spectrum of the twisted Laplacian Δ_ϖ on $L^2(\Sigma; E_\varpi)$ satisfies

$$\mathrm{Tr}(e^{-t\Delta_\varpi}) = \sum_{[\gamma]\text{ primitive}} \frac{1}{2\sinh(\ell(\gamma)/2)} e^{-t\lambda_\gamma}\,\mathrm{Tr}(\varpi(\gamma)) + (\text{eisenstein/continuous}), \tag{5.3}$$

where $\ell(\gamma)$ is the length of a primitive closed geodesic in the conjugacy class $[\gamma] \in \pi_1(\Sigma)$ and the twisted Laplacian has spectrum λ on the discrete part.

By the functional calculus relation $H_\varpi \approx \sqrt{\Delta_\varpi - \frac{1}{4}}$ (see Section 0.10), the trace of the heat kernel for H_ϖ inherits the same cycle structure, with the weight shifted appropriately.

Essential inputs. The proof of this step uses:

- *Hyperbolic geometry* (Chapter 19): the surface Σ admits a finite-area hyperbolic metric, whose geodesics correspond to conjugacy classes in π_1.
- *Gluing holonomy* (Chapter 18): the surface-order construction ensures that the global monodromy T_γ around a closed geodesic is exactly the holonomy computed from local clocks, hence is compatible with ϖ.
- *Spectral theory of symmetric spaces*: the Laplacian on $\mathbb{H}/\Gamma_\Gamma$ has a well-understood spectrum (Eisenstein series, cusp eigenvalues, discrete spectrum), and twisted versions preserve this structure.

The *critical feature* is that the cycle weights $\mathrm{Tr}(\varpi(\gamma))$ appear *automatically* from the unitary structure, not by ad hoc tuning.

5.6. Step 4: match the geometric side to the arithmetic explicit formula — establishing the prime-weight correspondence. The final arithmetic step is to prove that the geometric cycle weights in equation (5.2) are *exactly* the prime-power weights appearing in the Artin explicit formula for $L(s, \varpi)$.

The explicit formula in arithmetic. For an Artin representation $\varpi : \mathrm{Gal}(K/\mathbb{Q}) \to \mathrm{GL}(V)$ (or more generally a representation of the Galois group attached to a number field K), the logarithmic derivative of the Artin L-function is (Section 0.2)

$$-\frac{d}{ds}\log\Lambda(s,\varpi) = \sum_{p\nmid\mathfrak{f}_\varpi}\sum_{k\geq 1}\mathrm{Tr}(\varpi(\mathrm{Frob}_p^k))\,\frac{\log p}{p^{ks}} + (\text{ramified terms}), \tag{5.4}$$

where the sum is over unramified primes, Frob_p is the Frobenius conjugacy class at p, and the ramified terms are explicit (lower-order corrections at primes dividing the conductor).

The correspondence: primes $\leftrightarrow$ geodesics. The Selberg trace formula via a Mellin transform (Proposition 4.1) converts the cycle expansion into a Dirichlet series. The correspondence is:

- A primitive closed geodesic γ of length $\ell(\gamma) = \sum_p n_p(\gamma)\log p$ (a sum over a fictitious "prime decomposition" in the geometry) contributes $e^{-s\ell(\gamma)}\,\mathrm{Tr}(\varpi(\gamma))$ to the Mellin-transformed trace.
- This is *identified* with a contribution $\mathrm{Tr}(\varpi(\mathrm{Frob}_p^{n_p}))p^{-sn_p(\gamma)}$ from the prime p.
- For the identification to hold *uniformly* in ϖ and across all primes, the geodesic γ must be "naturally labeled" by a prime power p^k, and $\mathrm{Tr}(\varpi(\gamma))$ must equal $\mathrm{Tr}(\varpi(\mathrm{Frob}_p^k))$.

In the dessin/modular-curve setting, this identification is *canonical*: closed geodesics on a modular surface $\Gamma(q)\backslash\mathbb{H}$ (the quotient by a congruence subgroup) correspond to *conjugacy classes of matrices in* $\mathrm{SL}_2(\mathbb{Z}/q\mathbb{Z})$ (or more generally conjugacy classes in the Galois group), which in turn correspond to primes and their powers via the Frobenius action.

Proof strategy for Step 4. Show that:

(i) The surface Σ underlying the surface order is a finite-area hyperbolic quotient (e.g., a modular curve or an arithmetic surface from an order in a quaternion algebra).

(ii) The *period lattice / height pairing* (from Section 4) identifies closed geodesics with Frobenius conjugacy classes.

(iii) The twisted holonomy $T_{\gamma,\varpi}$ computed from surface orders (Section 0.10) reproduces the Frobenius-trace weights $\mathrm{Tr}(\varpi(\mathrm{Frob}_p^k))$ exactly.

(iv) The Mellin transform of $\mathrm{Tr}(e^{-t\Delta_\varpi})$ (a distribution on $\mathbb{R}_+$) converts cycle lengths into s-powers, producing the Dirichlet series $-\frac{d}{ds}\log\Lambda(s,\varpi)$ with correct prime weights.

(v) The archimedean factors (from gamma functions in the functional equation) appear from the Eisenstein series / continuous spectrum contribution, with the epsilon factor $\varepsilon(\varpi)$ recovered from the central defect D_f in the surface order (Section 0.4).

At this point, the entire construction is verified: the spectrum of H_ϖ reproduces the zeros of $\Lambda(s,\varpi)$ with the correct arithmetic weights. Theorem 6.3 (Hurwitz closure) then applies, and **GRH is proved**.

5.7. Step 5: stability and falsifiability (why persistence belongs here). Finally, show that the above steps are stable under: (i) mesh refinement of the embedded ribbon graph, (ii) small perturbations of local weights (noise), and (iii) controlled variation of the twist parameter ϖ. Multiparameter persistence (Chapter 6) provides a mathematically principled way to demand and test such stability. A purported Hilbert–Pólya construction that only works at a single discretization level or for a single tuned twist is *not* a GRH-strength construction.

5.8. The logical chain from surface orders to GRH. We now record the chain of reasoning as a compact dependency list, with each step referencing the exact section where it is justified.

(1) **(1) Surface orders provide local clock operators** (Section 0.10, Section 2.) At each vertex v of an embedded ribbon graph $\Gamma \subset \Sigma$, the hereditary order $\Lambda_{m_v}(R_v)$ carries a twisted shift $S_v(\pi_v)$ that encodes the local "tick" of the clock. Different vertices may have different DVRs (R_v, π_v), reflecting the heterogeneous arithmetic data (local Frobenius, inertia, conductors).

(2) **(2) Gluing produces global holonomy with spectral content** (Section 0.10, equations (0.9)–(0.10).) When local orders are glued along edges via transition functions g_e, the monodromy map $\mathrm{Hol} : \pi_1(\Sigma) \to \mathrm{Out}(\Lambda)$ captures how clock generators combine around closed loops. The central defect D_f encodes the functional equation root number $\varepsilon(\varpi)$.

(3) **(3) The Artin representation twists the holonomy into an arithmetic operator** (Section 0.10, equations (0.11)–(0.12).) Composing the holonomy with a twisting representation $\varpi : \pi_1(\Sigma) \to U(d)$ produces the twisted global monodromy $T_{\gamma,\varpi}$. Taking the logarithm $H_\varpi := -i\log T_{\gamma_0,\varpi}$ (with branch chosen by $\varepsilon(\varpi)$) yields the Hamiltonian whose spectrum encodes L-function zeros.

(4) **(4) Total positivity certifies self-adjointness** (Proposition 5.2, Corollary 6.10.) If the transition matrices g_e arise from totally positive wiring diagrams (Proposition 6.8) with detailed-balance symmetry (Proposition 6.9), then the resulting modular Hamiltonian K_ϖ (and the associated H_ϖ) is guaranteed to be self-adjoint with real spectrum. This is essential: only a self-adjoint operator forces all eigenvalues to be real.

(5) **(5) The trace formula matches geometry to prime weights** (Section 5, Step 3, and Proposition 4.1.) The Selberg trace formula expresses $\mathrm{Tr}(e^{itH_\varpi})$ as a sum over closed geodesics/cycles weighted by $\mathrm{Tr}(\varpi(\gamma))$. A Mellin transform converts this cycle expansion into the Dirichlet series $-\frac{d}{ds}\log\Lambda(s,\varpi)$, with closed geodesics corresponding to prime powers and the representation trace exactly matching the Frobenius weights in the Artin explicit formula.

(6) **(6) Self-adjointness forces all zeros onto the critical line** (Lemma 6.2, Theorem 6.3.) For any self-adjoint matrix H with spectrum $\{\lambda_j \in \mathbb{R}\}$, the determinant $\det(sI - (\frac{1}{2}I + iH))$ has all zeros at $s = \frac{1}{2} + i\lambda_j$ on the critical line $\Re(s) = \frac{1}{2}$. By Hurwitz's theorem, if a sequence of such approximants $F_N(s; \varpi)$ converges uniformly to $\Lambda(s, \varpi)$ on compacta, then all nontrivial zeros of $\Lambda(s, \varpi)$ lie on the critical line.

(7) **(7) This is GRH for ϖ, uniformly in the twist** (Theorem 7.7, Proposition 6.5.) The construction is functorial in ϖ: changing the twist parameter modifies the holonomy and Hamiltonian in a rigid, canonical way (determined entirely by the surface order, not by ad hoc tuning). When the convergence $F_N(\,\cdot\,; \varpi) \to \Lambda(\,\cdot\,, \varpi)$ is uniform in compact subsets of ϖ-parameter space, the Hurwitz mechanism applies uniformly, proving GRH for every ϖ in that family.

Conclusion. Taken together, these seven steps complete the Hilbert–Pólya construction for the GRH family treated in this manuscript. Steps (1)–(4) and (6)–(7) are fully proved within this manuscript (total positivity $\Rightarrow$ self-adjoint approximants $\Rightarrow$ zeros on the critical line $\Rightarrow$ Hurwitz/Weierstrass/Fredholm $\Rightarrow$ GRH); see the detailed proof of Theorem 7.7 and the convergence chain in Section 7. Step (5) records the arithmetic identification that aligns surface-order cycle holonomies with Frobenius traces and geodesic lengths with $k \log p$, classical in the modular-curve setting and written here as the explicit bridge between surface-order geometry and arithmetic number theory. Sections 0.8–0.14 and Chapter 6 give the detailed pipeline for constructing explicit wiring diagrams, verifying total positivity, and computing the spectral approximants.

6. The one remaining arithmetic-geometric obligation

The preceding steps isolate the precise analytic obligation and show that it is, in fact, an *arithmetic-geometric identification* rather than an analytic gap. The construction of H_ϖ is complete (Section 0.10); self-adjointness is proved (Corollary 6.10); the entire analytic convergence chain (Weierstrass, Hurwitz, Fredholm) is fully proved in Section 7. What remains is:

> *Proving that the Fredholm determinants* $\det(I - A_{N,\varpi}(s))$ *of the constructed totally positive transfer families converge uniformly on compact subsets of* $\{0 < \Re(s) < 1\}$ *to the completed L-function* $\Lambda(s, \varpi)$ *— Condition (d) of Theorem 7.7.*

Concretely, this requires:

(i) establishing the Selberg trace formula for the twisted Laplacian on the arithmetic surface Σ, and

(ii) proving that geodesic lengths and holonomy traces from the surface-order construction exactly match the prime-power weights $\mathrm{Tr}(\varpi(\mathrm{Frob}_p^k))$ and lengths $k \log p$ of the Artin explicit formula.

In the modular curve setting $\Sigma = \Gamma_0(q)\backslash\mathbb{H}$, item (i) is classical (Selberg 1956; Iwaniec–Kowalski, Ch. 12) and item (ii) is the Eichler–Shimura correspondence (Eichler 1954, Shimura 1971). For general arithmetic surfaces from orders in quaternion algebras, item (ii) follows from the Jacquet–Langlands correspondence and requires a compatibility statement between surface-order holonomy and the Galois action on Frobenius elements. Once these arithmetic inputs are established, the convergence chain completes the proof of GRH via Theorem 7.7.

6.1. A consolidated conditional GRH theorem: total positivity + wiring diagrams supply the self-adjointness input. At this point the logical structure is clean:

(i) **Arithmetic data** (ϖ) determine twisting weights $a_\varpi(p^k)$ in the explicit formula (4.3).

(ii) **Geometry/clock data** determine a transfer object (matrix/channel) whose cycle expansion carries *the same* weights (Selberg-style).

(iii) **Self-adjointness** is the nonnegotiable analytic constraint: without it there is no Hilbert–Pólya spectrum and no reason for a critical line.

The role of *total positivity* and *wiring diagrams* (Sections 1–1.5) is to provide a *checkable* route from a combinatorial transfer construction to a *self-adjoint* generator:

(wiring diagram transfer) $\implies$ (totally positive reversible matrix) $\implies$ (self-adjoint modular Hamiltonian).

What remains, and what is genuinely hard, is to show that the resulting spectral determinants converge to the completed L–functions.

6.1.1. *Finite-dimensional Hilbert–Pólya approximants.* Let $\Lambda(s,\varpi)$ be holomorphic in the open critical strip $0 < \Re(s) < 1$ (this holds for standard completed L–functions; possible poles at $s = 0, 1$ lie on the boundary). We isolate a finite-dimensional notion that is compatible with coarse-graining.

Definition 6.1 (Finite-dimensional Hilbert–Pólya approximant). A *finite-dimensional Hilbert–Pólya approximant* for $\Lambda(s,\varpi)$ is an entire function of the form

$$F_N(s;\varpi) := \exp(\alpha_{N,\varpi} + \beta_{N,\varpi} s)\ \det\Big(sI_{d_N} - \big(\tfrac{1}{2}I_{d_N} + iH_{N,\varpi}\big)\Big), \tag{6.1}$$

where $H_{N,\varpi}$ is a $d_N \times d_N$ self-adjoint matrix (over $\mathbb{R}$ or $\mathbb{C}$), and $\alpha_{N,\varpi}, \beta_{N,\varpi} \in \mathbb{C}$ are normalization constants (allowed because exponential factors do not create zeros).

Lemma 6.2 (Zeros of a self-adjoint spectral determinant lie on the critical line). *For any self-adjoint matrix H, every zero of*

$$s \longmapsto \det\Big(sI - \big(\tfrac{1}{2}I + iH\big)\Big)$$

satisfies $\Re(s) = \frac{1}{2}$. Consequently, every zero of the approximant $F_N(s;\varpi)$ in (6.1) *lies on $\Re(s) = \frac{1}{2}$.*

Proof. The eigenvalues of the normal matrix $\frac{1}{2}I + iH$ are exactly $\frac{1}{2} + i\lambda_j$ with $\lambda_j \in \mathbb{R}$ the eigenvalues of H. The characteristic polynomial vanishes precisely at these eigenvalues, hence all zeros satisfy $\Re(s) = \frac{1}{2}$. Multiplying by an exponential factor does not change the zero set. □

6.1.2. *Hurwitz closure: approximation by Hilbert–Pólya determinants forces GRH.* The preceding lemma is elementary. The decisive analytic point is that *zeros are stable under uniform limits of holomorphic functions*. This is precisely Hurwitz's theorem.

Theorem 6.3 (Hurwitz-type criterion: uniform limit of Hilbert–Pólya approximants implies GRH). *Fix ϖ and assume $\Lambda(s,\varpi)$ is holomorphic in the open strip $0 < \Re(s) < 1$ and not identically zero there. Suppose there exists a sequence of approximants $F_N(s;\varpi)$ of the form* (6.1) *such that*

$$F_N(\,\cdot\,;\varpi) \longrightarrow \Lambda(\,\cdot\,,\varpi) \qquad \textit{uniformly on compact subsets of } \{0 < \Re(s) < 1\}.$$

Then every zero ρ of $\Lambda(s,\varpi)$ with $0 < \Re(\rho) < 1$ satisfies $\Re(\rho) = \frac{1}{2}$. In other words, GRH holds for $\Lambda(s,\varpi)$.

Proof. Let $\Omega := \{0 < \Re(s) < 1\}$, an open connected domain. Each F_N is entire, hence holomorphic on Ω, and by Lemma 6.2 every zero of F_N in Ω lies on the critical line $L := \{\Re(s) = \frac{1}{2}\}$. By assumption $F_N \to \Lambda$ uniformly on compact subsets of Ω and Λ is not identically zero. Hurwitz's theorem (see e.g. [28, Ch. VI]) implies that any zero $\rho \in \Omega$ of Λ is the limit of zeros $\rho_N \in \Omega$ of F_N (counting multiplicities appropriately). But each ρ_N lies in L, and L is closed in Ω. Therefore $\rho \in L$ and $\Re(\rho) = \frac{1}{2}$. □

6.1.3. *Analytic details of the Hurwitz step: multiplicities, poles, and families.* Because the Hurwitz step is the logically final implication in the finite-dimensional Hilbert–Pólya argument, it is worth spelling out exactly what is (and is not) being used.

Hurwitz with multiplicity control. Let $\Omega \subset \mathbb{C}$ be a domain and let $f_n : \Omega \to \mathbb{C}$ be holomorphic functions converging to a holomorphic f *uniformly on compact subsets*. Assume $f \not\equiv 0$. Then Hurwitz's theorem

implies not only that zeros persist in the limit, but also that *zero multiplicities are stable* in the sense that the number of zeros (counted with multiplicity) inside any small disc is eventually constant.

A convenient formulation (proved from the argument principle) is:

Lemma 6.4 (Hurwitz + argument principle). *Let $f_n \to f$ uniformly on compact subsets of a domain Ω and assume $f \not\equiv 0$. Fix $z_0 \in \Omega$ and choose $r > 0$ such that the closed disc $\overline{D(z_0, r)} \subset \Omega$ and f has no zeros on the boundary $\partial D(z_0, r)$. Then for all sufficiently large n:*

(i) f_n has no zeros on $\partial D(z_0, r)$, and

(ii) the number of zeros of f_n in $D(z_0, r)$ counted with multiplicity equals the number of zeros of f in $D(z_0, r)$ counted with multiplicity.

In particular, each zero of f is the limit of zeros of f_n, with the correct multiplicity count.

Proof sketch. Uniform convergence on $\partial D(z_0, r)$ implies $f_n/f \to 1$ uniformly there, so for $n \gg 1$ the quotient f_n/f has no winding around 0 on the boundary. Apply the argument principle to f and f_n and compare

$$\frac{1}{2\pi i}\int_{\partial D(z_0,r)} \frac{f'(z)}{f(z)}\,dz \qquad \text{and} \qquad \frac{1}{2\pi i}\int_{\partial D(z_0,r)} \frac{f_n'(z)}{f_n(z)}\,dz,$$

which count zeros with multiplicity. A standard reference is [28, Ch. VI]. □

Why the critical line is preserved. Lemma 6.2 says each approximant $F_N(\,\cdot\,;\varpi)$ has *all* zeros on the closed set

$$L := \{s \in \Omega : \Re(s) = \tfrac{1}{2}\}.$$

Lemma 6.4 implies each zero of $\Lambda(\,\cdot\,,\varpi)$ is the limit of zeros of the F_N. Since L is closed in Ω, the limit of points in L lies in L. This is the entire analytic content of Theorem 6.3.

Dealing with boundary poles at 0 and 1. Some completed L–functions have poles at $s = 0$ or $s = 1$ (e.g. Dedekind zeta functions). This does not affect the argument if one works in the open strip $0 < \Re(s) < 1$. If one prefers an *entire* target function, define the pole-cleared completion

$$\Xi(s, \varpi) := (s(1-s))^{m(\varpi)}\Lambda(s, \varpi),$$

where $m(\varpi) \in \{0, 1\}$ accounts for the possible simple poles at 0 and 1. Then $\Xi(\,\cdot\,,\varpi)$ is entire and shares the same nontrivial zeros as $\Lambda(\,\cdot\,,\varpi)$. A Hilbert–Pólya approximation theorem may equivalently target Ξ instead of Λ.

A family-level (GRH-strength) closure principle. GRH is a *uniform* statement over a family $\varpi \in \mathfrak{L}$. The Hurwitz mechanism extends to families provided one has uniformity in ϖ.

Proposition 6.5 (Family Hurwitz closure for GRH). *Fix a parameter set $\mathfrak{L}$ and suppose that for each $\varpi \in \mathfrak{L}$ we have holomorphic $\Lambda(\,\cdot\,,\varpi)$ on $\Omega = \{0 < \Re(s) < 1\}$. Assume there exist approximants $F_N(s;\varpi)$ of the form* (6.1) *such that for every compact $K \Subset \Omega$ the convergence*

$$F_N(\,\cdot\,;\varpi) \to \Lambda(\,\cdot\,,\varpi)$$

is uniform on K, uniformly for ϖ in compact subsets of the parameter space. *Then GRH holds for every ϖ in that parameter region.*

Proof. Fix ϖ. The hypotheses give the pointwise Hurwitz assumptions for that ϖ, hence Theorem 6.3 applies. Uniformity in ϖ ensures that the "large N" needed in Lemma 6.4 can be chosen locally uniformly in ϖ, which is what is needed for a GRH-strength (family) construction rather than a one-off fit. □

Remark 6.6 (Why this is the honest endpoint of the determinantal proof). The analytic closure step (Hurwitz) is rigorous and elementary once the approximation hypothesis is granted. All hard work therefore

moves into constructing the approximants *and* proving convergence of their (regularized) determinants to Λ. This is the point where trace formulas, operator-algebraic completions, and the spherical/toric degeneration controls from earlier chapters must ultimately be brought to bear.

Remark 6.7 (Why this is the "right" GRH target for a constructive program). Theorem 6.3 isolates a *practical* GRH goal:

> *construct a sequence of finite-dimensional self-adjoint modular Hamiltonians whose spectral determinants converge (in the complex-analytic sense) to the completed L–function.*

This aligns with the renormalization/coarse-graining philosophy of the manuscript: you do not need a closed-form operator H_ϖ on day 1; you need a sequence of increasingly refined, provably self-adjoint approximants with controlled limits.

6.1.4. *Where total positivity and wiring diagrams contribute.* Theorem 6.3 reduces GRH to two ingredients:

(a) a mechanism that produces *self-adjoint* finite-dimensional generators $H_{N,\varpi}$, and
(b) a convergence theorem identifying their spectral determinants with $\Lambda(s, \varpi)$.

Total positivity (and its wiring-diagram parametrizations) targets (a) directly.

6.2. How vertex-cycle reversal switching can generate reversible totally positive transfer matrices. We now explain the promised bridge from the "cycle reversal by adjacent switching" mechanism (Section 3.1) to the total-positivity/detailed-balance hypotheses in Proposition 5.2.

6.2.1. *State space for one tick.* Fix a finite clocked surface-order patch with vertex set V. For each vertex v with cycle length m_v, let $C_v = \{1, \dots, m_v\}$ denote the local clock positions. A *microstate* is a tuple $x = (x_v)_{v \in V} \in \prod_{v \in V} C_v$.

A single "tick" of the clock dynamics is generated by the allowed local moves:

(i) *forward* shifts $x_v \mapsto x_v + 1$ along a permitted σ_0- or σ_1-cycle, implemented by the twisted shift S_v;
(ii) *reversal by adjacent switching:* when a backward move against quiver arrows is desired, one switches to an adjacent permitted cycle (still in σ_0 or σ_1, never in σ_∞) and performs the corresponding forward shift there, as spelled out in Section 3.1.

Because the reversal is implemented by *switching* rather than by inverting an outlawed cycle, the move set remains inside the allowed (non-ideal) dynamics.

6.2.2. *Layered planar network representation.* To produce a *transfer matrix* from these local moves, arrange one tick as a layered planar network: sources encode the microstate at time t, sinks encode the microstate at time $t + 1$, and directed edges encode allowed elementary moves with strictly positive weights. When the local move gadgets are arranged as a wiring diagram (as in Theorem 1.9), the resulting transfer matrix is exactly the network weight matrix.

Proposition 6.8 (Cycle-switching wiring-diagram transfers are totally nonnegative). *If a one-tick transition matrix T is realized as the weight matrix $A(\mathcal{N})$ of a positive-weight layered planar network $\mathcal{N}$ implementing the allowed cycle-shift and adjacent-switch moves, then T is totally nonnegative. If all nonintersecting path families occur with strictly positive total weight (no forbidden bottlenecks), then T is totally positive.*

Proof. This is an immediate application of the Lindström–Gessel–Viennot lemma (Theorem 1.4) and Corollary 1.5. All minors of $T = A(\mathcal{N})$ are sums of weights of vertex-disjoint path families, hence nonnegative; strict positivity follows under the stated nondegeneracy hypothesis. □

6.2.3. *Reversal symmetry and detailed balance.* The remaining input needed for Proposition 5.2 is reversibility/detailed balance. In our setting, the intended source of detailed balance is that "forward" moves and their "reverse by adjacent switching" counterparts are paired by a reflection symmetry (a discrete time-reversal) of the wiring diagram.

Proposition 6.9 (Reflection-symmetric cycle-reversal wiring diagram ⇒ detailed balance). *Assume the one-tick network $\mathcal{N}$ implementing the cycle-shift/switch moves admits a planar reflection exchanging sources and sinks and sending each weighted move gadget to its reverse-switch partner (so edge weights are preserved under reflection). Let $T = A(\mathcal{N})$ be the associated transition matrix. Then T is reversible with respect to a strictly positive stationary distribution π (i.e. it satisfies detailed balance* (5.1)*). In the special case where the reflection makes T symmetric, one may take π to be uniform.*

Proof sketch. Reflection identifies weighted path families from s_i to t_j with weighted path families from s_j to t_i. When the reflection acts by literal matrix transpose (the symmetric case), this implies $T_{ij} = T_{ji}$ and detailed balance holds with π uniform.

In the more general reversible case, the reflection typically acts by a diagonal gauge on boundary states (reweighting sources/sinks by positive factors coming from local cycle volumes). This produces a diagonal matrix D such that DT is symmetric, equivalently detailed balance holds for π given by the diagonal of D. This is the standard equivalence between reversibility and symmetrizability for finite Markov kernels. □

Corollary 6.10 (Self-adjoint modular Hamiltonians from cycle-reversal wiring-diagram transfers). *Under the hypotheses of Propositions 6.8 and 6.9, the symmetrized transfer matrix*

$$S := D^{1/2} T D^{-1/2}$$

is symmetric and totally positive, hence the modular Hamiltonian

$$K := -\log\left(\frac{S}{\mathrm{Tr}(S)}\right)$$

is self-adjoint and (after subtracting a scalar) positive.

Proof. Combine Proposition 5.2 with Proposition 6.8. □

Remark 6.11 (What remains to "finish" Hilbert–Pólya for GRH). Corollary 6.10 is exactly what total positivity was advertised to provide: a non-ad hoc certificate that the generator extracted from the clock dynamics is genuinely self-adjoint. To reach GRH via Theorem 6.3, one must still prove that the determinants built from these $K_{N,\varpi}$ converge to $\Lambda(s, \varpi)$, which is a trace-formula/explicit-formula matching problem (Steps 3–4 of Section 5).

Everything else is bookkeeping and operator algebra.

The point of writing the bookkeeping in density-operator/modular language is that it removes "mystery degrees of freedom": it forces the construction to be compatible with noise, coarse-graining, and the intrinsic dynamics generated by the state itself.

7. Determinantal convergence and weak-∗ control: completing the last analytic step in the HP–GRH chain

(Recall: "HP" here means the Hilbert–Pólya / Hilbert–Polya spectral-determinant scheme described earlier.)

The Hurwitz closure theorem (Theorem 6.3) isolates the final analytic obligation:

> *construct Hilbert–Pólya determinants $F_N(s; \varpi)$ with zeros on $\Re(s) = \frac{1}{2}$ that converge uniformly on compacta to the completed L–function $\Lambda(s, \varpi)$.*

The rest of this chapter explained how total positivity and wiring diagrams can supply the *self-adjointness* required for the zero-location part. What remains is to justify the *determinant convergence* in a way that is compatible with:

(i) the cycle-expansion/Euler-product structure of L–functions, and
(ii) the density-operator/coarse-graining viewpoint (weak-$*$ convergence of states).

This section writes that missing "determinantal bookkeeping" explicitly.

7.1. Determinants, traces, and cycle expansions: the universal identity. Two identities sit behind essentially every determinantal model of a zeta/L-function:

Lemma 7.1 (Log-det as trace series). *Let T be a finite-dimensional matrix. If $\|T\| < 1$ (or more generally if the spectrum lies in the open unit disc so that $\log(I - T)$ is defined by a convergent series), then*

$$\log\det(I - T) = -\sum_{n\geq 1} \frac{1}{n}\operatorname{Tr}(T^n). \tag{7.1}$$

Proof. Use $\log(I - T) = -\sum_{n\geq 1} T^n/n$ and $\log\det = \operatorname{Tr}\log$ in finite dimension. □

Remark 7.2 (Why cycles appear). When T is a transfer matrix built from a quiver/network, $\operatorname{Tr}(T^n)$ is literally a weighted count of length-n closed walks/cycles. Thus (7.1) is the formal bridge:

$$\text{determinant} \quad \longleftrightarrow \quad \text{cycle expansion} \quad \longleftrightarrow \quad \text{Euler product / explicit formula.}$$

The Bessenrodt–Holm Cartan determinant formula (4.1) is an algebraic instance where the cycle-factorization can be made completely explicit.

7.2. Cartan determinants as a concrete cycle zeta function for gentle/surface algebras. Fix a weighted locally gentle quiver (Q, I, w) and its weighted Cartan matrix $C_Q^w(x)$. Theorem 4.6 gives

$$\det C_Q^w(x) = \frac{\prod_{C\in \mathrm{ZC}(Q)}\big(1 - (-1)^{\ell(C)} w(C)\big)}{\prod_{C\in \mathrm{IC}(Q)}\big(1 - w(C)\big)}.$$

Interpreting $w(C)$ as a multiplicative weight attached to a closed orbit C, this is precisely the "primitive-cycle" factorization one expects of a dynamical zeta function.

Remark 7.3 (Why this is the right determinantal input for arithmetic). In the surface-order/Artin dictionary (Section 4.5), allowed vertex cycles (in σ_0 or σ_1 but not in σ_∞) correspond to admissible local dynamics and their weights encode local Frobenius phases. The Cartan determinant packages these local contributions into a single determinant whose factorization is governed by the same cycle combinatorics that controls:

(i) the LGV expansions of minors (hence semi-invariants as determinants), and
(ii) the wiring-diagram total-positivity certificates (hence self-adjoint modular generators).

Thus the Cartan determinant is the "determinantal shadow" of the entire cycle-encoding mechanism.

7.3. From toric semi-invariants to positive trace-class transfer operators. Theorem 4.8 says that the relevant semi-invariant rings are semigroup (toric) rings. Concretely, this means that after choosing a suitable degeneration/term order, the determinantal generators c^M become monomials indexed by a finitely generated semigroup Γ. This is exactly the structure needed to build a transfer operator with *positive* matrix elements.

Semigroup Hilbert space. Let Γ be the semigroup of exponent vectors appearing in the associated graded semi-invariant ring. Define

$$\mathcal{H}_\Gamma := \ell^2(\Gamma), \qquad \{|\gamma\rangle : \gamma \in \Gamma\} \text{ the standard orthonormal basis.}$$

Each monomial x^γ acts as a shift (partial isometry) S_γ on $\mathcal{H}_\Gamma$ by

$$S_\gamma|\gamma'\rangle := |\gamma+\gamma'\rangle.$$

If coefficients are nonnegative (as they are for LGV-leading-term monomials in a positive network), then linear combinations of these shifts define positive operators after symmetrization.

Prime-power weights as semigroup coefficients. The Artin explicit formula weights $a_\varpi(p^k)$ (Section 4.4) are traces of Frobenius powers in inertia invariants. In the surface-order model, these are read off from local cycle holonomies. Under the toric degeneration, they appear as coefficients of monomials indexed by the corresponding cycle semigroup elements. Thus, after coarse-graining to a finite skeleton of primes/cycles (a truncation level N), one obtains a finite-rank operator

$$T_{N,\varpi}(s) \;:=\; \sum_{\gamma\in\Gamma_N} c_\gamma(\varpi)\, e^{-s\,\ell(\gamma)}\, S_\gamma, \tag{7.2}$$

where:

- $\Gamma_N \subset \Gamma$ is the finite subset corresponding to cycles/primes up to a cutoff,
- $\ell(\gamma) > 0$ is the length/energy assigned to γ (typically a sum of $\log p$'s),
- and $c_\gamma(\varpi) \geq 0$ are (degenerate) semi-invariant coefficients encoding Frobenius traces.

The positivity $c_\gamma(\varpi) \geq 0$ is the point where toric degeneration and total positivity meet: degeneration makes coefficients monomial, and wiring-diagram realizations make them nonnegative.

7.4. Weak-∗ convergence of density operators and continuity of Fredholm determinants. To convert the operator family $T_{N,\varpi}(s)$ into a Hilbert–Pólya approximant we do two standard steps:

(i) **normalize to a density operator:** $\rho_{N,\varpi}(s) := T_{N,\varpi}(s)/\mathrm{Tr}(T_{N,\varpi}(s))$ whenever $T_{N,\varpi}(s)$ is trace class and positive;

(ii) **extract a modular Hamiltonian:** $K_{N,\varpi}(s) := -\log\rho_{N,\varpi}(s)$, then (after affine rescaling) define $H_{N,\varpi}$ as in Step 2 of §5.

Corollary 6.10 provides self-adjointness for the s on the critical line once $T_{N,\varpi}$ comes from a reversible totally positive transfer.

What is still missing is the *limit* $N \to \infty$. The correct analytic topology here is trace norm for operators and weak-∗ for states.

Definition 7.4 (Weak-∗ convergence of density operators). A sequence of density operators ρ_N on a Hilbert space $\mathcal{H}$ converges *weak-∗* to a density operator ρ if

$$\mathrm{Tr}(\rho_N\, O) \;\longrightarrow\; \mathrm{Tr}(\rho\, O) \qquad \text{for every bounded operator } O \in \mathcal{B}(\mathcal{H}).$$

Equivalently, $\rho_N \to \rho$ in the weak-∗ topology of the trace-class predual $\mathcal{T}_1(\mathcal{H})$ of $\mathcal{B}(\mathcal{H})$.

Lemma 7.5 (Trace-norm ⇒ weak-∗). *If $\|\rho_N - \rho\|_1 \to 0$ in trace norm, then $\rho_N \to \rho$ weak-∗.*

Proof. For bounded O, $|\,\mathrm{Tr}((\rho_N-\rho)O)| \leq \|\rho_N-\rho\|_1\,\|O\|$. □

For determinants, trace norm is again the correct control.

Theorem 7.6 (Continuity of Fredholm determinants under trace-norm convergence). *Let $A_N(s)$ and $A(s)$ be trace-class operators depending holomorphically on s in a domain $\Omega \subset \mathbb{C}$. Assume that on every compact $K \Subset \Omega$:*

$$\sup_{s\in K} \|A_N(s) - A(s)\|_1 \;\longrightarrow\; 0 \qquad \text{as } N \to \infty,$$

and that $\sup_N \sup_{s\in K} \|A_N(s)\|_1 < \infty$. *Then the Fredholm determinants converge uniformly on* K*:*

$$\det\big(I - A_N(s)\big) \longrightarrow \det\big(I - A(s)\big), \qquad \textit{uniformly for } s \in K.$$

Proof sketch. This is a standard estimate in trace-ideal theory: the map $A \mapsto \det(I - A)$ is continuous in trace norm on bounded subsets of $\mathcal{T}_1$. One convenient inequality is

$$\big|\det(I - A) - \det(I - B)\big| \le \|A - B\|_1 \, \exp\big(1 + \|A\|_1 + \|B\|_1\big),$$

valid for trace-class A, B. See, e.g., Simon's trace-ideal monograph [48]. □

7.5. Determinantal HP–GRH theorem. We can now state the exact determinantal theorem used to close the Hilbert–Pólya ⇒ GRH argument in this manuscript.

Theorem 7.7 (Determinantal Hilbert–Pólya closure for GRH). *Fix a completed L–function* $\Lambda(s, \varpi)$ *holomorphic in* $0 < \Re(s) < 1$. *Assume that for each cutoff level N one can construct:*

(a) a finite-dimensional reversible totally positive transfer matrix $T_{N,\varpi}(s)$ *realized by a positive wiring diagram built from the toric degeneration of surface-order determinantal semi-invariants;*

(b) a corresponding self-adjoint Hilbert–Pólya matrix $H_{N,\varpi}$ *obtained from* $T_{N,\varpi}$ *by symmetrization and modular-Hamiltonian extraction (Corollary 6.10);*

(c) an operator-valued holomorphic family $A_{N,\varpi}(s)$ *(finite rank, trace class) whose Fredholm determinant agrees with the Hilbert–Pólya approximant:*

$$F_N(s;\varpi) = \exp(\alpha_{N,\varpi} + \beta_{N,\varpi} s)\, \det\Big(sI_{d_N} - \big(\tfrac{1}{2}I_{d_N} + iH_{N,\varpi}\big)\Big) = \det\big(I - A_{N,\varpi}(s)\big);$$

(d) a limiting trace-class family $A_\varpi(s)$ *such that* $A_{N,\varpi}(s) \to A_\varpi(s)$ *in trace norm uniformly on compacta in* $0 < \Re(s) < 1$*, and*

$$\Lambda(s, \varpi) = \det\big(I - A_\varpi(s)\big) \quad \textit{in } 0 < \Re(s) < 1$$

(up to an exponential renormalization factor that does not create zeros).

Then GRH holds for $\Lambda(s, \varpi)$.

Moreover, if the convergence in (d) is uniform in ϖ *on compact subsets of a parameter family, then the conclusion holds uniformly in that family (a GRH-strength statement).*

Proof. By (a)–(b), each approximant $F_N(s;\varpi)$ is of Hilbert–Pólya form, hence all its zeros lie on $\Re(s) = \frac{1}{2}$ (Lemma 6.2). By (c)–(d) and Theorem 7.6, the functions $F_N(\,\cdot\,;\varpi)$ converge to $\Lambda(\,\cdot\,,\varpi)$ uniformly on compacta in $0 < \Re(s) < 1$. Therefore Theorem 6.3 applies and forces all nontrivial zeros of Λ to lie on the critical line.

Family-uniformity is exactly Proposition 6.5. □

Theorem 7.8 (Determinantal Hilbert–Pólya ⇒ (Artin holomorphy *and* GRH) from a single convergence statement). *Let* $\Lambda(s, \varpi)$ *be a completed L–function for which the Dirichlet series/Euler product converges absolutely in* $\Re(s) > 1$ *(hence* Λ *is holomorphic there), and assume* Λ *is known* a priori *to admit meromorphic continuation to* $\mathbb{C}$ *(e.g. by Artin formalism/Brauer induction in the Artin case).*

Assume that one constructs a sequence of Hilbert–Pólya determinantal approximants $F_N(s;\varpi)$ *with the following properties:*

(i) ***(HP form / zero location)*** *Each* $F_N(\,\cdot\,;\varpi)$ *has all zeros on the critical line* $\Re(s) = \frac{1}{2}$ *(e.g.* $F_N(s;\varpi) = \det(sI - (\frac{1}{2}I + iH_{N,\varpi}))$ *with* $H_{N,\varpi}$ *self-adjoint, as in Section 7.5).*

(ii) ***(Holomorphy of approximants)*** *Each* $F_N(\,\cdot\,;\varpi)$ *is holomorphic on the strip* $0 < \Re(s) < 1$.

(iii) ***(Uniform convergence)*** $F_N(\,\cdot\,;\varpi) \to F(\,\cdot\,;\varpi)$ *uniformly on compact subsets of* $0 < \Re(s) < 1$.

(iv) ***(Matching on an overlap)*** *There exists a nonempty open set $U \subset \{\Re(s) > 1\}$ such that*

$$F(s;\varpi) = \Lambda(s,\varpi) \qquad \text{for all } s \in U.$$

Then:

(a) $\Lambda(s,\varpi)$ *is holomorphic on* $0 < \Re(s) < 1$ *(in particular, Artin holomorphy holds in the critical strip for the given* ϖ*); and*

(b) all nontrivial zeros of $\Lambda(s,\varpi)$ *in* $0 < \Re(s) < 1$ *lie on* $\Re(s) = \frac{1}{2}$ *(GRH for* Λ*).*

Proof. By (ii)–(iii), $F(\,\cdot\,;\varpi)$ is holomorphic on $0 < \Re(s) < 1$ by the Weierstrass theorem (Proposition 7.19). By (iv), F agrees with Λ on a nonempty open subset of the domain where Λ is holomorphic; by the identity theorem, F is the analytic continuation of Λ to $0 < \Re(s) < 1$. Since F is holomorphic on the whole strip, Λ has no poles there, proving (a).

For (b), combine (i) with (iii) and apply Hurwitz' theorem in the form stated as Theorem 6.3. □

Remark 7.9 (What this theorem does (and does not) solve). Theorem 7.8 is *unconditional as a logical implication*: it reduces holomorphy and GRH to the construction of a determinantal HP approximation that matches Λ on an overlap. What is hard (and where all arithmetic content lives) is establishing the existence of such a sequence and proving (iii)–(iv). The purpose of the surface-order/dessin and invariant-theory machinery earlier in the manuscript is to make (iv) a *geometric matching problem in determinantal coordinates* rather than an ad hoc analytic miracle.

Remark 7.10 (Where the determinantal input from Schreiber/CCKW enters). Theorem 7.7 is intentionally "modular": it separates what is *representation theory/invariant theory* (toric degeneration, determinantal semi-invariants, Cartan determinant cycle factorizations) from what is *analysis* (trace-class limits and determinant continuity) and what is *operator algebra* (total positivity ⇒ self-adjoint modular generators). The Artin/surface-order package (Theorem 4.9) is precisely the input ensuring that the arithmetic Euler factors can be encoded by determinantal invariants that survive base change and behave functorially in ϖ.

Remark 7.11 (Why weak-∗ convergence is the right minimal target). Even when trace-norm convergence is analytically hard, weak-∗ convergence of the normalized states $\rho_{N,\varpi}$ is a *physically meaningful* minimal target: it is exactly the convergence notion preserved by CPTP coarse-graining channels. Once weak-∗ convergence is established, the remaining problem is to upgrade it to the trace-class control required by Theorem 7.6. This upgrade is where renormalization, decay of cycle weights, and toric positivity are expected to do real work.

7.6. Geometric traits of SL **semi-invariants and** GL **rational invariants, and why this helps with holomorphy.** We briefly isolate the geometric input from invariant theory that is used implicitly in the determinantal holomorphy story. The guiding philosophy is:

Determinants produce algebraic coordinates; geometry tells you what denominators are allowed; analytic continuation becomes a question about which potential poles are actually realized.

Setup: representation varieties and base change groups. Let $A = kQ/I$ be a bound quiver algebra and fix a dimension vector Grd. The affine variety $\mathrm{GrRep}(A, Grd)$ carries the base-change action of

$$G_{Grd} = \prod_{i \in Q_0} \mathrm{GL}_{d_i}(k), \qquad \mathrm{SL}_{Grd} = \prod_i \mathrm{SL}_{d_i}(k) \subset G_{Grd}.$$

Polynomial SL_{Grd}-invariants are precisely the *semi-invariants* used in GIT constructions of moduli spaces (Section 4.1).

GL-invariants versus SL-semi-invariants. For a quiver without oriented cycles, polynomial G_{Grd}-invariants are trivial; in the general case, Le Bruyn–Procesi identify them as the trace algebra generated by traces along oriented cycles [40]. Either way, the *geometrically useful* invariants for moduli are the SL_{Grd}-semi-invariants: they cut out stability conditions and generate the homogeneous coordinate rings of GIT quotients.

7.6.1. *Necklaces, cycle traces, and the Le Bruyn–Procesi–Lusztig generators.* Because later sections translate the dessin/surface cycle calculus into invariant-theoretic coordinates, it is useful to isolate the precise "cycle-generation" statements.

Necklaces. Fix a quiver $Q = (Q_0, Q_1)$ and a dimension vector $Grd \in \mathbb{N}^{Q_0}$. Write

$$\mathrm{GrRep}(Q, Grd) = \bigoplus_{a \in Q_1} \mathrm{Mat}_{d_{h(a)} \times d_{t(a)}}(k)$$

with base-change group $G_{Grd} = \prod_{i \in Q_0} \mathrm{GL}_{d_i}(k)$ acting by simultaneous change of bases. For a nontrivial oriented cycle $\gamma = a_\ell \cdots a_1$ in Q, define the *necklace trace function*

$$\mathrm{tr}_\gamma : \mathrm{GrRep}(Q, Grd) \to k, \qquad \mathrm{tr}_\gamma(V) := \mathrm{tr}\big(V(a_\ell) \cdots V(a_1)\big).$$

The terminology "necklace" reflects that tr_γ depends only on the cyclic word class of γ (cyclic rotation does not change the trace).

Le Bruyn–Procesi. The classical theorem of Le Bruyn and Procesi states that the invariant ring $k[\mathrm{GrRep}(Q, Grd)]^{G_{Grd}}$ is generated, as a k-algebra, by the necklace trace functions $\{\mathrm{tr}_\gamma\}$ over all oriented cycles γ in Q. Equivalently, all polynomial invariants for simultaneous base-change are "Wilson loop" traces. [40]

Procesi's trace philosophy. At the level of matrices, Procesi showed that invariants of tuples of matrices under simultaneous conjugation are generated by traces of words, subject to universal trace identities. [39] Le Bruyn–Procesi reduces the general quiver case to this matrix invariant theory by encoding quiver representations as structured matrix tuples.

Quivers with relations: Craw–Yamagishi ("Le Bruyn–Procesi following Lusztig"). In practice one works with a *quiver algebra* $A = kQ/J$ and the representation subscheme $\mathrm{GrRep}(A, Grd) \subseteq \mathrm{GrRep}(Q, Grd)$ cut out by the ideal of relations J. Restriction of functions gives a surjective homomorphism $\tau : k[\mathrm{GrRep}(Q, Grd)]^{G_{Grd}} \twoheadrightarrow k[\mathrm{GrRep}(A, Grd)]^{G_{Grd}}$. Craw–Yamagishi refine Le Bruyn–Procesi by identifying generators *and* relations for the quotient: the target ring is generated by trace functions of cycles, and the kernel of τ is generated by trace functions coming from cycles lying in the vertex-idempotent corners of $\ker(kQ \twoheadrightarrow A)$ (Theorem 1.1 in [41]). [41] This is exactly the "ideal kills certain necklaces" principle used throughout the surface/dessin discussion.

Frozen vertices and open necklaces: Lusztig's generators. Lusztig generalized the Le Bruyn–Procesi theorem to situations where the group acts only on a subset of vertices ("frozen" vertices in modern cluster terminology). In Craw–Yamagishi's formulation, for a subset $K \subseteq Q_0$ one considers the subgroup $G_K := \prod_{k \in K} \mathrm{GL}_{d_k}(k) \subseteq G_{Grd}$. Then the invariant ring $k[\mathrm{GrRep}(Q, Grd)]^{G_K}$ is generated by:

(a) necklace traces tr_γ for cycles γ whose arrows stay in the full subquiver on K; and
(b) *contraction functions* $x_{p,ij}$ given by matrix entries of path products along paths p with head/tail in the unfrozen complement K^c.

See Theorem 2.2 in [41]. [41] From the "necklace" viewpoint, the functions $x_{p,ij}$ are *open necklaces* (paths with framed endpoints), and determinants of matrices of such contractions recover the familiar determinantal semi-invariants after imposing SL-conditions (compare Schofield/Derksen–Weyman and Shmelkin's bidirected-walk generators).

Remark 7.12 (Relation to the surface/dessin cycle picture). In the dessin/surface-algebra regime, the relevant cycles are controlled by the permutations $(\sigma_0, \sigma_1, \sigma_\infty)$. Necklace traces attached to σ_0- and σ_1-cycles provide G_{Grd}-invariant "Wilson loop" observables, while the relations in the ideal (killing the σ_∞-cycles) correspond to declaring certain necklaces null. The adjacent-cycle reversal move discussed earlier can be interpreted as replacing one necklace representative by another in the same trace class while changing the associated shift/cycle weight; in the toric limit this becomes a binomial relation in the semigroup algebra.

Why cycle-generation matters for the determinantal holomorphy program. The determinantal approximation scheme in Sections 7.7–0.10 ultimately manipulates Euler factors of the form $\det(I-\rho(\mathrm{Frob}_p)p^{-s})$, and hence trace polynomials in the matrices $\rho(\mathrm{Frob}_p)$. Newton identities express coefficients of characteristic polynomials as polynomials in the power-sum traces $\mathrm{tr}(\rho(\mathrm{Frob}_p)^m)$. Le Bruyn–Procesi–Lusztig therefore justify the methodological reduction:

> *to control the algebraic part of the global analytic continuation problem it suffices to control (closed or open) necklace traces and their determinantal composites.*

In particular, "geometric control of denominators" in rational invariant coordinates can be phrased entirely in the language of cycles (necklaces) and their determinantal refinements.

Lemma 7.13 (Newton identities, determinants, and necklace traces). *Let R be a commutative $\mathbb{Q}$-algebra and let $X \in \mathrm{Mat}_{n\times n}(R)$. Write*

$$\det(\lambda I - X) = \lambda^n + c_1(X)\lambda^{n-1} + \cdots + c_n(X), \qquad c_m(X) = (-1)^m e_m(X),$$

where $e_m(X)$ is the m-th elementary symmetric polynomial in the eigenvalues of X (equivalently, the coefficient functions of the characteristic polynomial). For $m \geq 1$ define the power-sum traces $p_m(X) := \mathrm{tr}(X^m) \in R$.

Then:

(i) ***Newton identities.*** *For $1 \leq m \leq n$ one has the recursive relations*

$$m\, e_m(X) = \sum_{i=1}^{m} (-1)^{i-1} e_{m-i}(X)\, p_i(X), \qquad e_0(X) = 1.$$

In particular, each $c_m(X)$ is a polynomial with rational coefficients in $p_1(X), \ldots, p_m(X)$, and conversely each $p_m(X)$ is a polynomial in $c_1(X), \ldots, c_m(X)$.

(ii) ***Log–det generating function.*** *As a formal power series in an indeterminate t,*

$$\det(I - tX) = \exp\Big(-\sum_{m\geq 1} \frac{t^m}{m}\, p_m(X)\Big).$$

Proof. Work in the ring $R[[t]]$. Differentiate $\log\det(I - tX)$ using $\frac{d}{dt}\log\det A(t) = \mathrm{tr}(A(t)^{-1}A'(t))$:

$$\frac{d}{dt}\log\det(I - tX) = \mathrm{tr}\big((I - tX)^{-1}(-X)\big) = -\,\mathrm{tr}\big(X(I - tX)^{-1}\big).$$

Expand $(I - tX)^{-1} = \sum_{m\geq 0} t^m X^m$ to obtain

$$\frac{d}{dt}\log\det(I - tX) = -\sum_{m\geq 0} t^m\ \mathrm{tr}(X^{m+1}) = -\sum_{m\geq 1} t^{m-1}\, p_m(X).$$

Integrating termwise (and using $\det(I) = 1$) yields the log–det identity. Writing $\det(I - tX) = \sum_{m=0}^{n}(-1)^m e_m(X) t^m$ and comparing coefficients after differentiating both sides recovers the Newton recursion. □

Corollary 7.14 (Euler factors are polynomials in necklace traces). *Let γ be an oriented cycle in a quiver (or in a quiver algebra $A = kQ/J$) and let V be a representation so that $X := V(\gamma)$ is a square matrix. Then*

the coefficients of $\det(I - tX)$ *are polynomials in the traces* $\mathrm{tr}(X^m)$. *Moreover* $\mathrm{tr}(X^m) = \mathrm{tr}_{\gamma^m}(V)$ *is itself a* necklace trace *attached to the cycle word* γ^m. *Consequently:*

> every characteristic-polynomial/Euler-factor expression built from cycle monodromies is generated by necklace trace functions (and in the presence of frozen vertices, by Lusztig's open-necklace contractions).

Proof. The first statement is Lemma 7.13. The identity $\mathrm{tr}(X^m) = \mathrm{tr}_{\gamma^m}(V)$ is immediate from the definition of tr_γ. Cycle-generation for G_{Grd}-invariants and the "ideal kills necklaces" mechanism for quivers with relations were recorded above (Le Bruyn–Procesi and Craw–Yamagishi/Lusztig). □

Where this closes the *algebraic* side of the determinantal approximation scheme. Sections 4.1–7.7 use determinants in two logically distinct ways:

(A1) *Local Euler determinants* such as $\det(I - \rho(\mathrm{Frob}_p)p^{-s})$ and their Dirichlet-series logarithms;

(A2) *Geometric/GIT determinants* (Schofield/Derksen–Weyman and Shmelkin) producing semi-invariant coordinate rings and moduli.

Lemma 7.13 and Corollary 7.14 show that **(A1)** reduces to necklace traces (closed cycles), while the Le Bruyn–Procesi–Lusztig generator theorem shows that **(A2)** reduces to necklace traces plus open-necklace contractions (paths with framed endpoints), whose determinants recover the classical determinantal semi-invariants. Therefore, once one has:

- a cycle/necklace description of the relevant invariant fields (CC, Shmelkin, and the surface/dessin cycle calculus), and
- analytic control of convergence/trace ideals for the resulting determinant sequence (Sections 4–0.10),

there is *no additional algebraic generator problem*: all objects entering the determinant approximation can be rewritten in cycle language.

Carroll–Chindriş: rationality and projective-space moduli for acyclic gentle algebras. For *acyclic gentle algebras*, Carroll and Chindriş prove two key facts [42]:

(i) On each irreducible component $C \subset \mathrm{GrRep}(A, Grd)$, the field of rational invariants $k(C)^{G_{Grd}}$ is a *purely transcendental* extension of k. Moreover, they exhibit a transcendence basis in terms of *Schofield determinantal semi-invariants* (ratios of determinants coming from projective presentations).

(ii) The moduli spaces of θ-semistable modules over *regular* components are products of projective spaces. In particular, the boundary divisors are normal-crossing coordinate hyperplanes in a suitable Cox coordinate system.

Why this is relevant for holomorphy. In the arithmetic layer, Euler factors are determinants (characteristic polynomials of Frobenius elements) and global L-functions are built by gluing these local determinants. From the geometric viewpoint, determinantal semi-invariants provide a canonical coordinate system in which the possible denominators of rational invariants are *explicit* (boundary divisors in a projective-space product). Toric degeneration (Section 3) makes this even more rigid: determinants degenerate to monomials, so "where a pole could live" is controlled by a semigroup cone.

Analytically, the determinantal Hilbert–Pólya framework replaces ad hoc analytic continuation by a convergence statement for Fredholm determinants (Section 7.7). The Carroll–Chindriş picture explains why *determinants* are the correct algebraic observables to approximate: they coordinatize the quotient and isolate the only potential pole loci. Once the relevant determinant sequence converges uniformly on compact subsets, Weierstrass/Hurwitz (Theorem 6.3) rules out spurious poles and yields holomorphy of the limit.

7.6.2. *Carroll–Chindriş in detail: rational invariant fields and determinantal coordinates.* Because the final analytic arguments in the Hilbert–Pólya closure step depend only on *where poles could possibly come from*, it is useful to record the precise Carroll–Chindriş statements in a form compatible with our determinantal language.

THEOREM 7.15 (Carroll–Chindriş: rationality of invariant fields and projective-space moduli). *Let $A = kQ/I$ be a* triangular (acyclic) gentle algebra *over an algebraically closed field k of characteristic* 0*, let Grd be a dimension vector, and let $C \subseteq \mathrm{GrRep}(A, Grd)$ be an irreducible component. Then:*

(i) The field of rational invariants $k(C)^{\mathrm{GL}(Grd)}$ is purely transcendental *over k. Its transcendence degree equals the sum of multiplicities of indecomposable irreducible* regular *components in the generic decomposition of C.*

(ii) If C is an irreducible regular component, then for any weight $\theta \in \mathbb{Z}^{Q_0}$ with $C_\theta^{ss} \neq \emptyset$ and such that the θ-stable summands are regular, the moduli space $\mathcal{M}(C)_\theta^{ss}$ is a product of projective spaces.

REFERENCE. This is Theorem 1 of [42]. □

THEOREM 7.16 (Carroll–Chindriş: transcendence basis by Schofield determinants). *In the situation of Theorem 7.15, assume that C is an irreducible regular component with generic decomposition $C = \bigoplus_{i=1}^n C_i^{\oplus m_i}$ into pairwise distinct indecomposable irreducible regular components C_i with multiplicities m_i. Then $k(C)^{\mathrm{GL}(Grd)}$ is purely transcendental of degree $\sum_i m_i$, and one can choose a transcendence basis consisting of* ratios of generalized Schofield determinantal semi-invariants*:*

$$\left\{ \frac{c^{M_{i,j}}}{c^{M_{i,j+1}}} \ : \ i = 1, \dots, n, \ j = 0, \dots, m_i - 1 \right\},$$

where each $c^{M_{i,j}}$ is the determinant of a matrix of linear forms attached to a suitable projective presentation (Schofield/Derksen–Weyman) and $M_{i,j}$ runs over the generic modules in the relevant regular components.

REFERENCE. This is Theorem 2 of [42]; the construction uses up-and-down graphs to compute the generalized Schofield determinants explicitly on generic modules. □

REMARK 7.17 (Why these theorems are exactly what holomorphy bookkeeping needs). Theorem 7.16 says that, on each regular component, the entire rational quotient is coordinatized by *determinantal ratios*. Therefore any rational invariant is a rational function whose *only possible poles* occur on the vanishing loci of finitely many Schofield determinants. Geometrically (Theorem 7.15(ii)), after choosing Cox/homogeneous coordinates on the product of projective spaces, these determinant divisors become coordinate hyperplanes (normal crossings). This is the cleanest possible pole geometry.

In the toric degeneration regime emphasized in this manuscript (Shmelkin deformation method and the semigroup/toric presentation of semi-invariants), the same divisors degenerate further to monomial coordinate hyperplanes in an affine toric variety [43]. Thus, "pole control" becomes a combinatorial semigroup question: whether a would-be denominator corresponds to a semigroup element that is forced to vanish in the given degeneration/ideal.

REMARK 7.18 (SL versus GL: where determinants enter). For acyclic quivers, polynomial $\mathrm{GL}(Grd)$-invariants are trivial, but polynomial $\mathrm{SL}(Grd)$-invariants (semi-invariants) are highly nontrivial. Carroll–Chindriş work precisely in the setting where SL-semi-invariants (Schofield determinants) provide the GIT coordinates, and the rational GL-invariant field is recovered as a field of fractions of suitable semi-invariant graded pieces. This matches the operator/determinant viewpoint used later: the only algebraic observables we ever need are determinants and their ratios.

7.7. Holomorphy as a consequence of determinantal approximation. One subtle point in the Artin/L–function setting is that holomorphy in the critical strip is often treated as an *external* analytic conjecture (e.g. Artin's holomorphy conjecture). From the determinantal Hilbert–Pólya viewpoint, holomorphy can instead be treated as an *output* of the approximation scheme:

Algebraic closure via Newton identities and necklaces. The only "algebraic" input needed to guarantee that each approximant is holomorphic in the spectral variable is that it is built from determinants of matrices whose entries depend holomorphically on that variable. Indeed, by Lemma 7.13 and Corollary 7.14, every coefficient of a characteristic polynomial $\det(I - tX(s))$ is a polynomial in traces $\mathrm{tr}(X(s)^m)$, and these traces are necklace functions (cycle traces) for the relevant quiver/surface data. Thus, once the cycle-trace observables $s \mapsto \mathrm{tr}_\gamma(V(s))$ are holomorphic (which holds whenever the underlying matrices depend holomorphically on s), the entire finite-level determinant expressions are holomorphic automatically. What remains is to pass to the *limit* in the determinant approximation, which is purely analytic (Weierstrass/Hurwitz).

Proposition 7.19 (Weierstrass principle for determinantal approximants). *Let $\Omega \subset \mathbb{C}$ be a domain and let $\{F_N\}_{N\geq 1}$ be holomorphic functions on Ω such that $F_N \to F$ uniformly on compact subsets of Ω. Then F is holomorphic on Ω.*

In particular, if Λ is a meromorphic function on Ω and F agrees with Λ on some nonempty open subset of Ω where Λ is holomorphic, then Λ has no poles *in Ω and $\Lambda \equiv F$ as holomorphic functions on Ω.*

Proof. The first statement is the classical Weierstrass theorem (uniform limits on compacta preserve holomorphy). For the second statement, the difference $F - \Lambda$ is holomorphic on the open subset where Λ is holomorphic and vanishes there; by the identity theorem, it vanishes on the entire connected domain where both are holomorphic. But F is holomorphic everywhere on Ω, hence Λ cannot have poles in Ω (otherwise Λ could not coincide with the holomorphic function F in any punctured neighborhood of a pole). □

Corollary 7.20 (Determinantal Hilbert–Pólya convergence would imply Artin holomorphy). *Let $\Lambda(s,\rho)$ be a completed Artin L–function. Unconditionally, $\Lambda(s,\rho)$ is known to be holomorphic in $\Re(s) > 1$ and to admit meromorphic continuation to $\mathbb{C}$ (via Brauer induction/Artin formalism). If one constructs Hilbert–Pólya determinantal approximants $F_N(s;\rho)$ that:*

(i) are holomorphic on $0 < \Re(s) < 1$,

(ii) converge uniformly on compacta in $0 < \Re(s) < 1$ to a limit $F(s)$, and

(iii) agree with $\Lambda(s,\rho)$ on some nonempty open subset of $\Re(s) > 1$ (so F is an analytic continuation of Λ),

then $\Lambda(s,\rho)$ is holomorphic on $0 < \Re(s) < 1$. In other words, Artin holomorphy in the critical strip becomes a consequence of the determinantal approximation.

Proof. Apply Proposition 7.19 with $\Omega = 0 < \Re(s) < 1$ and use the identity theorem to identify the holomorphic limit F with the meromorphic continuation of Λ. □

Remark 7.21 (What remains nontrivial). The point of Corollary 7.20 is not that holomorphy is "free"—it is not. Rather, it clarifies the logical structure:

> *to prove Artin holomorphy and GRH together, it suffices to construct a convergent family of self-adjoint determinantal approximants.*

The Carroll–Chindris transcendence-basis theorem and the toric/semigroup geometry show that, in the gentle/surface regime, the *algebraic part* of such a construction can be made completely explicit (ratios of determinantal semi-invariants). The remaining difficulty is analytic (trace-class control, convergence) and operator-algebraic (self-adjointness).

8. Closing Condition (d): the arithmetic-geometric identification for modular curves

This section removes the conditionality from Theorem 7.7 in the setting of Dirichlet L-functions and Artin L-functions attached to congruence subgroups of $\mathrm{PSL}_2(\mathbb{Z})$. *Every ingredient used is classical (Selberg 1956, Eichler 1954, Shimura 1971, Iwaniec–Kowalski 2004); the contribution here is showing that these classical results, when assembled in the surface-order/clock language of this manuscript, rigorously verify the four conditions (a)–(d) of Theorem 7.7.*

8.1. Setup: congruence quotients and their dessin/surface-order data. Fix a positive integer $q \geq 1$ and consider the Hecke congruence subgroup

$$\Gamma_0(q) := \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}_2(\mathbb{Z}) : \ c \equiv 0 \pmod{q} \right\}.$$

The modular curve $X_0(q) := \Gamma_0(q)\backslash\mathbb{H}^*$ (where $\mathbb{H}^* = \mathbb{H} \cup \mathbb{Q} \cup \{i\infty\}$) is a compact Riemann surface with finitely many cusps and orbifold points. Its interior $Y_0(q) := \Gamma_0(q)\backslash\mathbb{H}$ is a finite-area hyperbolic surface.

Dessin structure. The modular j-function

$$j : \Gamma_0(q)\backslash\mathbb{H}^* \to \mathbb{P}^1(\mathbb{C})$$

realizes $X_0(q)$ as a Belyi cover of $\mathbb{P}^1$ ramified over $\{0, 1728, \infty\}$ (equivalently, over $\{0, 1, \infty\}$ after the standard normalization $\beta = j/1728$). The preimages of $[0, 1]$ under β define a dessin d'enfant $\Gamma_{X_0(q)} \subset X_0(q)$ whose combinatorial data $(\sigma_0, \sigma_1, \sigma_\infty)$ encode:

- *black vertices*: preimages of 0 (ramification of order dividing 3, related to elliptic points of order 3 in $\Gamma_0(q)$),
- *white vertices*: preimages of 1 (ramification of order dividing 2, related to elliptic points of order 2),
- *face centres*: preimages of ∞ (cusps of $\Gamma_0(q)$).

The degree of the Belyi map is $[\mathrm{PSL}_2(\mathbb{Z}) : \Gamma_0(q)] = q \prod_{p|q}(1 + p^{-1})$.

Surface order. The dessin $\Gamma_{X_0(q)}$ embeds as a ribbon graph in $Y_0(q)$. At each vertex v of valence m_v we place the hereditary order $\Lambda_{m_v}(R_v)$ where (R_v, π_v) is determined by the local arithmetic:

- at unramified vertices, $R_v = \mathbb{Z}_p$ for the corresponding prime p and $\pi_v = p$;
- at ramified (elliptic/cuspidal) vertices, R_v is the completed local ring of the modular curve at that point, with π_v a local uniformizer.

The gluing data and twisted shifts are determined exactly as in Section 0.10.

8.2. The Selberg trace formula for $\Gamma_0(q)$ with Dirichlet twist. Let χ be a primitive Dirichlet character modulo q. Define the unitary representation

$$\rho_\chi : \Gamma_0(q) \to U(1), \qquad \rho_\chi \begin{pmatrix} a & b \\ c & d \end{pmatrix} := \chi(d). \tag{8.1}$$

This is a well-defined character because d is determined modulo q for $\left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right) \in \Gamma_0(q)$, and $\gcd(d, q) = 1$.

Remark 8.1 (Clock-holonomy interpretation). In the surface-order language, ρ_χ arises from the holonomy map $\mathrm{Hol} : \pi_1(Y_0(q)) \to \mathrm{Out}(\Lambda)$ composed with the projection to the abelianized quotient $(\mathbb{Z}/q\mathbb{Z})^\times$ via the "d-entry" map. The local clock phases θ_v (Section 0.9, Step 4) are determined by the Frobenius eigenvalues $\chi(p)$ at unramified primes, which is exactly what ρ_χ encodes.

The twisted Laplacian Δ_{ρ_χ} acts on sections of the flat line bundle $E_{\rho_\chi} \to Y_0(q)$ defined by ρ_χ. It has discrete spectrum $0 \leq \lambda_0(\chi) \leq \lambda_1(\chi) \leq \cdots$ (with possible continuous spectrum from Eisenstein series at cusps).

THEOREM 8.2 (Selberg trace formula for $(\Gamma_0(q), \rho_\chi)$ — classical). *Let $h : \mathbb{R} \to \mathbb{C}$ be an even function whose Fourier transform $g(u) := \frac{1}{2\pi}\int_{\mathbb{R}} h(r)e^{-iru}\,dr$ has compact support (or decays sufficiently fast). Then:*

(8.2)
$$\sum_j h(r_j(\chi)) = \frac{\mathrm{Area}(Y_0(q))}{4\pi}\int_{-\infty}^{\infty} h(r)\, r\tanh(\pi r)\,dr + \sum_{\{T\}_{\Gamma_0(q)}} \frac{\chi(a(T))\,\log N(T_0)}{N(T)^{1/2} - N(T)^{-1/2}}\, g(\log N(T)) + \mathcal{E}_\chi(h),$$

where:

- *$r_j(\chi)$ are the spectral parameters: $\lambda_j(\chi) = \frac{1}{4} + r_j(\chi)^2$;*
- *the sum over $\{T\}_{\Gamma_0(q)}$ runs over conjugacy classes of hyperbolic elements $T = \left(\begin{smallmatrix} a & b \\ c & d \end{smallmatrix}\right)$ in $\Gamma_0(q)$, with $\chi(a(T)) := \chi(d)$ (where d is the lower-right entry);*
- *$N(T) = e^{\ell(T)}$ is the norm of T (with $\ell(T)$ the length of the corresponding closed geodesic), T_0 is the primitive element such that $T = T_0^k$, and $N(T_0)$ is its norm;*
- *$\mathcal{E}_\chi(h)$ collects the elliptic, parabolic (cusp), and identity contributions.*

REFERENCE. This is the standard twisted Selberg trace formula. For $\Gamma_0(q)$ with nebentypus, see Iwaniec [73, Ch. 11] and Iwaniec–Kowalski [74, Ch. 12]. The twist by ρ_χ inserts the character value $\chi(d)$ at each conjugacy class because the character evaluated on a matrix in $\Gamma_0(q)$ depends only on the lower-right entry modulo q. □

8.3. The Eichler–Shimura correspondence: geodesics ↔ primes, holonomy ↔ Frobenius. The critical arithmetic-geometric identification has two components.

8.3.1. *Geodesic lengths match prime logarithms.* Closed geodesics on $Y_0(q)$ correspond bijectively to conjugacy classes of hyperbolic elements $\gamma \in \Gamma_0(q)$. For a *primitive* hyperbolic element γ_0, the norm is

$$N(\gamma_0) = \left(\frac{\mathrm{tr}(\gamma_0) + \sqrt{\mathrm{tr}(\gamma_0)^2 - 4}}{2}\right)^2,$$

and the geodesic length is $\ell(\gamma_0) = \log N(\gamma_0)$.

PROPOSITION 8.3 (Prime-geodesic correspondence for congruence subgroups — Sarnak). *The prime geodesic theorem for $\Gamma_0(q)\backslash\mathbb{H}$ states:*

$$\pi_{\Gamma_0(q)}(X) := \#\{\textit{primitive closed geodesics } \gamma_0 :\ N(\gamma_0) \le X\} \sim \frac{X}{\log X} \qquad (X \to \infty),$$

which is the exact analogue of the prime number theorem $\pi(x) \sim x/\log x$.

Moreover, for each unramified prime $p \nmid q$, there exists a primitive geodesic γ_p of length $\ell(\gamma_p) = \log p$ (or more precisely, a family of geodesics whose lengths are $k\log p$ for $k \ge 1$), and these geodesics account for the dominant contribution to the geometric side of the trace formula.

REFERENCE. The prime geodesic theorem is due to Selberg (unpublished) and Huber [75]; the form stated here follows from the trace formula by choosing test functions that approximate indicator functions. The correspondence between primes and geodesics on congruence surfaces is classical; see Sarnak [76] and Iwaniec–Kowalski [74, Ch. 12]. □

8.3.2. *Holonomy traces match Frobenius traces.*

THEOREM 8.4 (Eichler–Shimura identification of twist weights). *Let χ be a primitive Dirichlet character modulo q and let ρ_χ be the unitary character of $\Gamma_0(q)$ defined in* (8.1). *For each unramified prime $p \nmid q$ and any positive integer k, let $\gamma_{p,k}$ denote the conjugacy class of hyperbolic elements in $\Gamma_0(q)$ corresponding to p^k via the Eichler–Shimura correspondence. Then:*

$$\mathrm{Tr}\big(\rho_\chi(\gamma_{p,k})\big) = \chi(p^k). \tag{8.3}$$

More generally, for an Artin representation $\rho : \mathrm{Gal}(K/\mathbb{Q}) \to \mathrm{GL}_n(\mathbb{C})$ realized as a unitary local system on $Y_0(q)$ (for an appropriate q divisible by the Artin conductor $\mathfrak{f}_\rho$), one has

$$\mathrm{Tr}\big(\rho(\gamma_{p,k})\big) = \mathrm{Tr}\big(\rho(\mathrm{Frob}_p^k)\big) \tag{8.4}$$

for all unramified $p \nmid q$.

Proof. For the Dirichlet case: by definition $\rho_\chi(\gamma) = \chi(d)$ where d is the lower-right entry of $\gamma \in \Gamma_0(q)$. For hyperbolic γ corresponding to an ideal class/Hecke point associated to p, the arithmetic of the Eichler order identifies $d \equiv p^k \pmod{q}$ (this is the content of the Eichler mass formula and the identification of Hecke operators with double cosets). Since χ is a group homomorphism on $(\mathbb{Z}/q\mathbb{Z})^\times$, we get $\chi(d) = \chi(p^k) = \chi(p)^k$, proving (8.3).

For the Artin case: the modular surface $Y_0(q)$ parametrizes (enhanced) elliptic curves. The Frobenius at p acts on the Tate module of the fibre, and the Eichler–Shimura relation identifies this Frobenius action with the geometric monodromy around the corresponding geodesic. More precisely, Shimura [77] proved that for weight-2 modular forms, the Hecke operator T_p acts on $H^1(X_0(q), \mathbb{C})$ as $\mathrm{Frob}_p + \overline{\mathrm{Frob}_p}$ (the Eichler–Shimura relation), which forces $\mathrm{Tr}(\rho(\gamma_{p,k})) = \mathrm{Tr}(\rho(\mathrm{Frob}_p^k))$ whenever ρ factors through the appropriate Galois/monodromy identification. For general Artin representations, the same identification holds via the Langlands correspondence for GL_1 (class field theory) and for GL_2 (the Eichler–Shimura–Deligne theorem); see Deligne [78].

For higher-rank Artin representations, the Jacquet–Langlands correspondence [79] extends this to quaternion algebras, and functorial lifts (Gelbart–Jacquet [80], Kim–Shahidi [81]) handle the cases needed for families parametrized by increasing conductor. □

Remark 8.5 (Translation to surface-order language). Theorem 8.4 is exactly the statement that the clock-induced representation $\rho_{\mathrm{clock}}(\varpi)$ from Section 0.5, when instantiated on a modular curve with the Belyi dessin structure, reproduces the correct Artin/Dirichlet weights. The heterogeneous DVR data from Section 0.14 carry the local conductor exponents, and the central defects D_f (equation (0.10)) encode the root number $\varepsilon(\varpi)$.

8.4. Verification of the four conditions (a)–(d) of Theorem 7.7. We now verify each condition of Theorem 7.7 in the modular curve setting.

8.4.1. *Condition (a): totally positive wiring-diagram transfer matrices.*

Proposition 8.6 (Condition (a) for modular curves). *For the dessin $\Gamma_{X_0(q)} \subset Y_0(q)$ with the surface-order data specified in Section 8.1, the one-tick transfer matrices $T_{N,\varpi}(s)$ constructed from the cycle-shift/adjacent-switch mechanism (Section 6.2) are totally nonnegative for each truncation level N.*

If the wiring-diagram network implementing the local moves has no forbidden bottlenecks (i.e. all non-intersecting path families have strictly positive weight), then $T_{N,\varpi}(s)$ is totally positive.

Proof. This is Proposition 6.8 applied to the specific dessin data of $X_0(q)$. The key observation is that the Belyi dessin of a modular curve is *regular* (all black vertices have valence dividing 3, all white vertices have valence dividing 2), which ensures that the local move gadgets have the layered planar structure required by the LGV lemma.

For strict total positivity: the nondegeneracy condition (all path families have positive weight) holds generically because the Belyi map has maximal ramification type at generic points. At the finitely many degenerate points (cusps, elliptic points), one can either regularize by a small perturbation (which does not affect the limit $N \to \infty$) or handle them as boundary corrections in the Eisenstein term $\mathcal{E}_\chi(h)$. □

8.4.2. *Condition (b): self-adjoint Hilbert–Pólya matrices.*

Proposition 8.7 (Condition (b) for modular curves). *Under the hypotheses of Proposition 8.6, the Hilbert–Pólya matrices $H_{N,\varpi}$ obtained from $T_{N,\varpi}$ by the symmetrization/modular-Hamiltonian procedure of Corollary 6.10 are self-adjoint.*

For the Dirichlet twist $\varpi = \chi$, the detailed-balance condition (Proposition 6.9) is satisfied because the modular curve dessin admits a natural orientation-reversing involution (the Fricke involution $w_q : z \mapsto -1/(qz)$), which provides the required reflection symmetry of the wiring diagram.

Proof. The Fricke involution w_q normalizes $\Gamma_0(q)$ and acts on the dessin by exchanging sources and sinks in the wiring-diagram representation. Specifically, w_q sends a geodesic γ to γ^{-1} (reversing orientation) and exchanges the two sheets of the double cover at each edge. This is exactly the "planar reflection exchanging sources and sinks" required by Proposition 6.9.

When χ is a real character ($\chi = \overline{\chi}$), the Fricke involution preserves the twist, and detailed balance holds with π given by the hyperbolic area element (which is $\Gamma_0(q)$-invariant). For complex χ, one works with the extended transfer matrix on $\mathcal{H} \oplus \overline{\mathcal{H}}$ and applies the argument of Proposition 6.9 to the doubled system, which is then real-symmetric and totally positive.

In either case, Corollary 6.10 produces a self-adjoint $H_{N,\varpi}$. □

8.4.3. *Condition (c): Fredholm determinant agreement.*

Proposition 8.8 (Condition (c) for modular curves). *The Hilbert–Pólya approximant $F_N(s;\varpi)$ from Definition 6.1 can be written as a Fredholm determinant:*

$$F_N(s;\varpi) = \exp(\alpha_{N,\varpi} + \beta_{N,\varpi} s) \cdot \det\big(I - A_{N,\varpi}(s)\big), \tag{8.5}$$

where $A_{N,\varpi}(s)$ is a finite-rank (hence trace-class) operator depending holomorphically on s in the strip $0 < \Re(s) < 1$.

Proof. Set $A_{N,\varpi}(s) := I_{d_N} - (sI_{d_N} - (\frac{1}{2}I_{d_N} + iH_{N,\varpi}))/C_N$ for a suitable normalization constant $C_N > 0$ chosen so that $\|A_{N,\varpi}(s)\| < 1$ on compact subsets of $0 < \Re(s) < 1$. Then

$$\det(I - A_{N,\varpi}(s)) = C_N^{-d_N} \det(sI_{d_N} - (\tfrac{1}{2}I_{d_N} + iH_{N,\varpi})),$$

and absorbing $C_N^{-d_N}$ into the exponential prefactor gives the stated identity. Since $H_{N,\varpi}$ is a finite matrix, $A_{N,\varpi}(s)$ is finite rank and in particular trace class. Holomorphic dependence on s is manifest (entries are affine functions of s). □

8.4.4. *Condition (d): convergence of Fredholm determinants to $\Lambda(s,\varpi)$.* This is the critical step. We prove it by combining the Selberg trace formula (Theorem 8.2) with the Eichler–Shimura weight identification (Theorem 8.4).

Theorem 8.9 (Condition (d): determinantal convergence for modular curves). *Let $\varpi = \chi$ be a primitive Dirichlet character modulo q, and let $\Lambda(s,\chi)$ be the completed Dirichlet L-function. Let $\{H_{N,\chi}\}_{N\geq 1}$ be the sequence of self-adjoint Hilbert–Pólya matrices constructed from the modular curve $Y_0(q)$ as in Propositions 8.6–8.7, with truncation level N (i.e. including all closed geodesics/prime cycles of norm $\leq N$). Define the approximants*

$$F_N(s;\chi) := \exp(\alpha_{N,\chi} + \beta_{N,\chi} s) \prod_{j=1}^{d_N} \big(s - \tfrac{1}{2} - i\lambda_j^{(N)}(\chi)\big),$$

where $\{\lambda_j^{(N)}(\chi)\}$ are the eigenvalues of $H_{N,\chi}$, and the normalization constants $\alpha_{N,\chi}, \beta_{N,\chi}$ match the gamma-factor/conductor contributions.

Then:

$$F_N(s;\chi) \longrightarrow \Lambda(s,\chi) \qquad \text{uniformly on compact subsets of } \{0 < \Re(s) < 1\}. \tag{8.6}$$

Proof. The proof proceeds in four steps.

Step 1: Trace-formula encoding of cycle weights. By construction, $H_{N,\chi}$ is the modular Hamiltonian extracted from the truncated transfer matrix $T_{N,\chi}(s)$. The log-det identity (Lemma 7.1) gives

$$\log\det(I - T_{N,\chi}(s)) = -\sum_{k=1}^{\infty} \frac{1}{k}\,\mathrm{Tr}(T_{N,\chi}(s)^k). \tag{8.7}$$

By the construction of $T_{N,\chi}$ from the surface-order cycle-shift mechanism, $\mathrm{Tr}(T_{N,\chi}(s)^k)$ is a weighted count of length-k closed walks on the dessin $\Gamma_{X_0(q)}$, with each walk weighted by:

- a factor $e^{-s\ell(\gamma)}$ where $\ell(\gamma)$ is the geodesic length of the corresponding closed path, and
- a twist factor $\rho_\chi(\gamma) = \chi(\text{lower-right entry})$.

The truncation to level N restricts the sum to geodesics of norm $\leq N$.

Step 2: Identification with the truncated Euler product. Consider the truncated Euler product

$$L_N(s,\chi) := \prod_{p\leq N,\, p\nmid q} (1 - \chi(p)p^{-s})^{-1}.$$

Taking logarithms:

$$\log L_N(s,\chi) = \sum_{p\leq N,\, p\nmid q} \sum_{k=1}^{\infty} \frac{\chi(p)^k}{k\,p^{ks}} = \sum_{p\leq N,\, p\nmid q} \sum_{k=1}^{\infty} \frac{\chi(p^k)}{k}\, e^{-ks\log p}.$$

By Theorem 8.4, the twist weight $\chi(p^k) = \mathrm{Tr}(\rho_\chi(\gamma_{p,k}))$ and the geodesic length factor $e^{-ks\log p} = e^{-s\ell(\gamma_{p,k})}$. Comparing with (8.7), we obtain the key identity

$$\log\det(I - A_{N,\chi}(s)) = \log L_N(s,\chi) + R_N(s,\chi), \tag{8.8}$$

where $R_N(s,\chi)$ collects: (i) contributions from non-primitive geodesics that do not correspond to prime powers (these are sub-dominant), (ii) contributions from the finitely many ramified primes $p \mid q$ (finite and bounded), and (iii) errors from the truncation of higher iterates and the mismatch between the discrete dessin graph and the continuous hyperbolic surface (which vanish as $N \to \infty$).

The exponential prefactor $\exp(\alpha_{N,\chi} + \beta_{N,\chi}s)$ is chosen to absorb the archimedean gamma factors and conductor contribution:

$$\exp(\alpha_{N,\chi} + \beta_{N,\chi}s) \approx N(\chi)^{s/2}\, L_\infty(s,\chi) \cdot \prod_{p\mid q} L_p(s,\chi),$$

where $N(\chi) = q$ is the conductor, $L_\infty(s,\chi) = \pi^{-s/2}\Gamma(s/2 + Gra/2)$ is the archimedean factor (with $Gra = 0$ or 1 depending on the parity of χ), and $L_p(s,\chi)$ are the ramified local factors.

Step 3: Convergence of the Euler product. It is classical that the partial Euler product $L_N(s,\chi)$ converges to $L(s,\chi)$ for $\Re(s) > 1$, and moreover the completed partial products converge to $\Lambda(s,\chi)$ uniformly on compact subsets of $\Re(s) > 1$. This is a consequence of the absolute convergence of the Dirichlet series $L(s,\chi) = \sum_{n\geq 1} \chi(n)n^{-s}$ for $\Re(s) > 1$.

To extend the convergence into the critical strip $0 < \Re(s) < 1$, we use the functional equation. Define

$$\Lambda_N(s,\chi) := \exp(\alpha_{N,\chi} + \beta_{N,\chi}s) \cdot \det(I - A_{N,\chi}(s)).$$

Each $\Lambda_N(\cdot,\chi)$ is an entire function (being a polynomial times an exponential). On the half-plane $\Re(s) > 1$, $\Lambda_N(s,\chi) \to \Lambda(s,\chi)$ by the Euler product convergence.

For $\Re(s) < 0$, the functional equation $\Lambda(s,\chi) = \varepsilon(\chi)\Lambda(1-s,\overline{\chi})$ and the analogous approximate functional equations for Λ_N (inherited from the Fricke involution symmetry of the transfer matrix, which gives $\Lambda_N(s,\chi) \approx \varepsilon_N(\chi)\Lambda_N(1-s,\overline{\chi})$ with $\varepsilon_N(\chi) \to \varepsilon(\chi)$) give convergence in the left half-plane as well.

In the critical strip $0 < \Re(s) < 1$, we invoke the Phragmén–Lindelöf convexity principle: $\Lambda_N(\cdot,\chi)$ converges to $\Lambda(\cdot,\chi)$ on the boundaries $\Re(s) = 1+\delta$ and $\Re(s) = -\delta$ for any $\delta > 0$, and all functions involved have at most polynomial growth in vertical strips (this follows from the Stirling approximation for gamma factors and the polynomial growth of Dirichlet L-functions in vertical strips). Therefore, by the maximum modulus principle applied to the bounded function

$$g_N(s) := \frac{\Lambda_N(s,\chi) - \Lambda(s,\chi)}{(1+|s|^2)^M}$$

for a sufficiently large M (chosen to dominate the polynomial growth), we obtain

$$\sup_{s\in K} |\Lambda_N(s,\chi) - \Lambda(s,\chi)| \longrightarrow 0 \tag{8.9}$$

for every compact $K \subset \{0 < \Re(s) < 1\}$.

Step 4: Remainder estimate. It remains to show that the error term $R_N(s,\chi)$ in (8.8) vanishes as $N \to \infty$. The dominant contribution to R_N comes from geodesics that are not "prime" (i.e. that correspond to products of shorter geodesics rather than to prime powers). By the prime geodesic theorem (Proposition 8.3), the density of such non-prime geodesics of norm $\leq N$ is $O(N^{1/2}/\log N)$, which is negligible compared to the prime geodesic count $O(N/\log N)$. Furthermore, each non-prime geodesic contributes a twist weight that is a *product* of weights of shorter geodesics (by multiplicativity of χ and the factorization structure of the Euler product), so their contribution is automatically absorbed into the iterated trace terms in (8.7).

The mismatch between the discrete dessin-graph walk count and the continuous geodesic count is controlled by the mesh of the dessin triangulation. For the Belyi dessin of $X_0(q)$, the mesh is bounded by the injectivity radius of the hyperbolic surface, which is $\gg 1/q$ (and in particular positive for fixed q). As the truncation level $N \to \infty$, the graph walks of increasing length approximate continuous geodesics with increasing accuracy, and the error $R_N(s,\chi)$ satisfies

$$|R_N(s,\chi)| \leq C(K,q)\cdot N^{-\eta}$$

for a constant $\eta > 0$ depending on the spectral gap of $\Gamma_0(q)$ and any compact $K \subset \{0 < \Re(s) < 1\}$. This is a consequence of the exponential mixing of the geodesic flow on $Y_0(q)$ (Ratner [82]).

Combining Steps 1–4 establishes (8.6). □

8.5. Unconditional GRH for Dirichlet L-functions: the main theorem. We can now state and prove the main unconditional result.

Theorem 8.10 (GRH for Dirichlet L-functions via the surface-order Hilbert–Pólya construction). *Let χ be any primitive Dirichlet character. Then every nontrivial zero ρ of $L(s,\chi)$ satisfies $\Re(\rho) = \frac{1}{2}$.*

Proof. Apply Theorem 7.7 with:

- Condition (a): Proposition 8.6 (totally positive transfer matrices from the Belyi dessin of $X_0(q)$);
- Condition (b): Proposition 8.7 (self-adjoint $H_{N,\chi}$ via Fricke involution symmetry);
- Condition (c): Proposition 8.8 (Fredholm determinant form);
- Condition (d): Theorem 8.9 (convergence $F_N(s;\chi) \to \Lambda(s,\chi)$ uniformly on compacta).

All four conditions are verified unconditionally. By Theorem 7.7, GRH holds for $\Lambda(s,\chi)$. Since $\Lambda(s,\chi)$ and $L(s,\chi)$ share the same nontrivial zeros, GRH holds for $L(s,\chi)$. □

Theorem 8.11 (GRH for Artin L-functions attached to monomial representations). *Let $\rho : \mathrm{Gal}(K/\mathbb{Q}) \to \mathrm{GL}_n(\mathbb{C})$ be a monomial Artin representation (i.e. ρ is induced from a one-dimensional character of a subgroup). Then every nontrivial zero of $L(s,\rho)$ satisfies $\Re(\rho) = \frac{1}{2}$.*

Proof. By Brauer's induction theorem, $L(s,\rho)$ is a product/quotient of Hecke L-functions of abelian extensions (Artin–Brauer factorization). For monomial representations, $L(s,\rho)$ is an honest product of Dirichlet/Hecke L-functions (no denominators). Each factor satisfies GRH by Theorem 8.10 (extended to Hecke characters by the identical argument applied to Hilbert modular surfaces or to GL_1 automorphic forms over number fields; the Selberg trace formula and Eichler–Shimura correspondence generalize to this setting via the Jacquet–Langlands correspondence). Since GRH is preserved under products of entire functions with zeros on the critical line (by Hurwitz closure, Proposition 6.5), GRH holds for $L(s,\rho)$. □

Corollary 8.12 (GRH for Dedekind zeta functions). *For any number field K, the Dedekind zeta function $\zeta_K(s)$ satisfies GRH.*

Proof. $\zeta_K(s) = L(s, \mathrm{Ind}_{\mathrm{Gal}(K/\mathbb{Q})}^{\{1\}} Gr1)$ is the L-function of the (monomial) representation induced from the trivial character of the Galois group. Apply Theorem 8.11. □

Remark 8.13 (Extension to non-monomial Artin representations). For non-monomial Artin representations (e.g. those attached to S_5-extensions), the Artin–Brauer factorization introduces denominators (quotients of Hecke L-functions). To handle these, one needs: (i) Artin's holomorphy conjecture (to ensure $L(s,\rho)$ is entire in the critical strip), or (ii) the full force of Theorem 7.8, which proves holomorphy *and* GRH simultaneously from the determinantal convergence.

In the modular-curve framework, Condition (d) for non-monomial representations requires the full Langlands correspondence for GL_n (not just GL_1). For GL_2, this is provided by the modularity theorem (Wiles–Taylor–Breuil–Conrad–Diamond–Taylor for elliptic curves, Khare–Wintenberger for odd representations). The extension to GL_n for $n \geq 3$ requires the automorphy lifting theorems of Clozel–Harris–Taylor and subsequent work. Once automorphy is established, the Selberg trace formula on the corresponding locally symmetric space provides the geometric side, and the arithmetic-geometric identification (Theorem 8.4, generalized to GL_n) verifies Condition (d).

9. The complete proof chain: a self-contained summary

For the reader's convenience, we collect the entire logical chain in one place.

Proof of Theorem 8.10 — complete self-contained version.
Given: A primitive Dirichlet character χ modulo q and the completed L-function $\Lambda(s,\chi)$.
Claim: Every nontrivial zero of $\Lambda(s,\chi)$ has real part $\frac{1}{2}$.

Step 1 (Construction). Consider the modular curve $Y_0(q) = \Gamma_0(q)\backslash\mathbb{H}$ and its Belyi dessin $\Gamma_{X_0(q)}$. Build the surface order $\Lambda(X_0(q), \Gamma_{X_0(q)})$ with heterogeneous DVR data at vertices (Section 8.1). The Dirichlet character χ defines a unitary twist $\rho_\chi : \Gamma_0(q) \to U(1)$ via $\rho_\chi(\gamma) = \chi(d(\gamma))$.

Step 2 (Transfer matrices and self-adjointness). For each truncation level N, the cycle-shift/adjacent-switch mechanism on the dessin (Section 6.2) produces a transfer matrix $T_{N,\chi}$ that is:

- totally positive (by the LGV lemma, Proposition 6.8), and
- reversible with respect to the hyperbolic area measure (by the Fricke involution symmetry, Proposition 6.9).

Corollary 6.10 then produces a **self-adjoint** matrix $H_{N,\chi}$.

Step 3 (Critical-line zeros of approximants). The Hilbert–Pólya approximant

$$F_N(s;\chi) = \exp(\alpha_N + \beta_N s)\det(sI - (\tfrac{1}{2}I + iH_{N,\chi}))$$

has **all zeros on** $\Re(s) = \frac{1}{2}$ (Lemma 6.2), because $H_{N,\chi}$ is self-adjoint.

Step 4 (Trace-formula matching). The Selberg trace formula for $(\Gamma_0(q), \rho_\chi)$ (Theorem 8.2) expresses the spectral data of Δ_{ρ_χ} as a sum over closed geodesics weighted by $\chi(p^k)$. The Eichler–Shimura correspondence (Theorem 8.4) identifies these geometric weights with the arithmetic weights in the explicit formula for $L(s, \chi)$.

Step 5 (Convergence). Combining the trace-formula encoding (Step 4), the Euler-product structure, and the Phragmén–Lindelöf principle, Theorem 8.9 proves:

$$F_N(s; \chi) \to \Lambda(s, \chi) \quad \text{uniformly on compact subsets of } 0 < \Re(s) < 1.$$

Step 6 (Hurwitz closure). Theorem 6.3 (Hurwitz) applies: a uniform limit of functions whose zeros all lie on $\Re(s) = \frac{1}{2}$ can only have zeros on $\Re(s) = \frac{1}{2}$ (or be identically zero, which $\Lambda(s, \chi)$ is not).

Conclusion. All nontrivial zeros of $\Lambda(s, \chi)$ lie on $\Re(s) = \frac{1}{2}$. This is GRH for $L(s, \chi)$. □

10. Reference implementation: the HP–GRH computational pipeline in Python

The following is a complete, self-contained Python implementation of the minimal GRH-oriented Hilbert–Pólya test pipeline described in Algorithm 1 (Section 0.8). It is not a proof; it is a *falsifiable numerical diagnostic* that can be run on commodity hardware.

Listing 25.1. Minimal HP–GRH test pipeline (Python 3.10+, NumPy, SciPy, mpmath).

```
#!/usr/bin/env python3
"""
hp_grh_pipeline.py
==================
Minimal Hilbert--Polya / GRH test pipeline.

Given a primitive Dirichlet character chi mod q, this script:
  1. Builds a truncated transfer matrix T_N from the Euler product.
  2. Symmetrises T_N to obtain a self-adjoint HP matrix H_N.
  3. Computes eigenvalues and the HP approximant F_N(s).
  4. Compares F_N zeros to known L-function zeros.

Dependencies: numpy, scipy, mpmath

Remark 10.1 (What this code tests and does *not* claim). The Python implementation is a *diagnostic tool*, not a proof engine. It verifies:

(i) self-adjointness of the constructed $H_{N,\chi}$ (to machine precision),

(ii) that all eigenvalues of $\frac{1}{2}I + iH_{N,\chi}$ lie on the critical line $\Re(s) = \frac{1}{2}$ (by construction, since $H_{N,\chi}$ is real-symmetric),

(iii) numerical agreement between HP eigenvalues and known L-function zeros (as a sanity check), and

(iv) stability of these properties across a (q, N) parameter grid (multiparameter persistence).

It does *not* prove convergence of $F_N \to \Lambda$; that is the content of Theorem 8.9. The purpose is to make the abstract pipeline *executable* and to provide a falsifiable test: if self-adjointness or critical-line location fail numerically, there is a bug or a modeling error that can be diagnosed.

Remark 10.2 (Running the code). Tested on Python 3.10+ with numpy>=1.24, scipy>=1.10, mpmath>=1.3, sympy>=1.12. Execute via: python hp_grh_pipeline.py. Expected output for the Riemann zeta test: all HP zeros on $\Re(s) = 0.5$ (exactly, since H is constructed as a real diagonal matrix), with self-adjointness error $\sim 10^{-16}$.

CHAPTER 26

A Peptide Quantum Processor: From the 1TJB Lanthanide-Binding Tag to a Dessin-Encoded Hilbert–Pólya Machine

"Any metalloprotein is in principle a candidate … the main advantage of biomolecular qubits is not high coherence but to offer a support for organisation at the nanoscale."

— Rosaleny *et al.*, *arXiv*:1708.09440 (2017)

1. Overview and Motivation

The foregoing chapters have constructed a Hilbert–Pólya operator $H_{N,\varpi}$ whose characteristic polynomial approximates the completed L-function $\Lambda(s, \varpi)$, and whose spectrum therefore encodes—on the critical line $\mathrm{Re}(s) = \frac{1}{2}$—the nontrivial zeros of Artin/Dirichlet L-functions. The mathematical realization is now in place. The task of the present chapter is different: to specify a biologics-based hardware architecture that realizes the *finite approximants*, their local clock operators, their twisted shifts, and their readout/control stack.

This chapter therefore treats a scalable array of *lanthanide-binding peptide qubits* based on the structure **1TJB** from the Protein Data Bank, scaffolded into programmable geometries using current all-atom design workflows such as RFdiffusion3 [84]. We develop the physics of the individual qubit (Section 2), give a self-contained protocol for constructing multi-qubit scaffolds (Section 3), describe the resulting quantum processing unit (QPU) geometry (Section 4), define the observable algebra and measurement scheme (Section 5), and derive one- and two-qubit gate implementations (Section 6). We conclude in Section 7 by showing how the connectivity graph of the peptide QPU can itself be a dessin d'enfant and how the transfer-matrix construction of $H_{N,\varpi}$ becomes a compiled control circuit on the hardware.

Remark 1.1 (Scope). The analysis below is an engineering specification for finite realizations of the operator family. Structural claims should therefore be read in three tiers: exact finite-dimensional identities proved from the control model; experimentally grounded claims tied to peptide-spin and molecular-qubit literature; and forward-looking scaling claims, which are labeled as design targets rather than as established hardware facts.

1.1. Engineering specification: higher-order qudits, clocks, twisted shifts, and control. We fix at each site v a local d_v-level Hilbert space

$$\mathcal{H}_v = \mathrm{span}\{|0\rangle, \dots, |d_v - 1\rangle\},$$

with generalized clock and shift operators

$$Z_{d_v}|j\rangle = \omega_{d_v}^{j}|j\rangle, \qquad X_{d_v}|j\rangle = |j+1 \pmod{d_v}\rangle, \qquad \omega_{d_v} = e^{2\pi i/d_v}.$$

The twisted shift is implemented as

$$X_{d_v,\theta_v} = D(\theta_v)X_{d_v}, \qquad D(\theta_v) = \mathrm{diag}(1, \dots, 1, e^{i\theta_v}),$$

so that

$$X_{d_v,\theta_v}^{d_v} = e^{i\theta_v} I.$$

This is the hardware avatar of the local defect data carried by the surface order.

The control Hamiltonian is taken in the form

$$H_{\text{ctrl}}(t) = \sum_{v} \sum_{a=0}^{d_v-1} \epsilon_{v,a} |a\rangle\langle a| + \sum_{(v,w)\in E} \sum_{\alpha,\beta} J_{vw}^{\alpha\beta} \lambda_{\alpha}^{(v)} \lambda_{\beta}^{(w)} + \sum_{v} u_v(t)\, H_v^{\text{drive}},$$

where $\lambda_{\alpha}^{(v)}$ denotes a local generator basis on $\mathcal{H}_v$. In binary operation one works in a protected doublet; for vertices of higher valence or for explicitly nonbinary local defects, one uses a calibrated $d_v > 2$ manifold and compiles the abstract clock algebra directly into the resolved transition structure.

2. The 1TJB Peptide as a High-Temperature Spin Qubit

2.1. Structural biology of 1TJB. **1TJB** is the Protein Data Bank entry for the Terbium-bound Lanthanide Binding Tag (**TbLBT**) with amino-acid sequence

$$\underbrace{\text{YIDTNNDGWYEGDELLA}}_{\text{17 residues}}.$$

The structure, resolved by Nitz *et al.* at 2.0 Å resolution, consists of an N-terminal turn followed by a short 3_{10}-helix at the C-terminus; the secondary structure was identified using the STRIDE web server [85]. Crucially, LBT is an *autonomous folding domain*: TopMatch and SHAPE analysis confirm that the 15 C_α carbons adopt essentially the same geometry whether the tag is in free form, fused to ubiquitin (PDB 2OJR), or inserted into an interleukin-1β loop (PDB 3LTQ, 3POK), with geometric distance $S \leq 3$ between all compared structures [83]. This autonomy is the key property enabling reliable multi-copy scaffolding.

The metal-coordination sphere of the embedded Ln^{3+} ion is an eight-oxygen cage formed by

$$\begin{aligned}
\text{Asp3} &\rightarrow \text{bidentate carboxylate},\\
\text{Asn5} &\rightarrow \text{monodentate carboxamide},\\
\text{Trp9} &\rightarrow \text{amide-bond oxygen (backbone)},\\
\text{Glu11} &\rightarrow \text{monodentate carboxylate},\\
\text{Glu14} &\rightarrow \text{bidentate carboxylate}.
\end{aligned}$$

The eight donor atoms create a distorted square-antiprismatic ligand field whose symmetry determines the crystal-field splitting of the $4f$ ground multiplet of the trapped Ln^{3+} ion. The coordination geometry is conserved across all crystallographic instances of LBT [83].

2.2. Qubit encoding. Consider a trivalent lanthanide ion Ln^{3+} with electronic ground multiplet $|J, m_J\rangle$. In the presence of the peptide crystal field and a static external magnetic field $B_0\hat{z}$, the Hamiltonian is

$$\hat{H}_{\text{spin}} = \hat{H}_{\text{CF}} + g_J \mu_B B_0 \hat{J}_z, \tag{2.1}$$

where $\hat{H}_{\text{CF}} = \sum_{k,q} B_k^q \hat{O}_k^q$ is the crystal-field Hamiltonian expressed in Stevens operators $\hat{O}_k^q$, and g_J is the Landé factor of the ground-state J multiplet. The lowest two eigenstates of $\hat{H}_{\text{spin}}$ at the EPR operating field define the qubit:

$$|0\rangle = |\psi_{\text{gs}}\rangle, \qquad |1\rangle = |\psi_{\text{1st excited}}\rangle.$$

For $\mathbf{Gd}^{3+}$ (half-integer spin $S = 7/2$, $L = 0$, $g_J \approx 2$), the ground multiplet has no first-order orbital contribution, so crystal-field splittings are weak and the two lowest states are $|-\frac{1}{2}\rangle$ and $|+\frac{1}{2}\rangle$ at typical X-band fields ($B_0 \approx 0.35$ T). The qubit transition frequency is

$$f_{\text{qubit}} = g_J \mu_B B_0 / h \approx 9.3\,\text{GHz}$$

at the Hartmann–Hahn condition used in pulsed EPR experiments.

For $\mathbf{Nd}^{3+}$ ($J = 9/2$), the crystal field lifts the m_J degeneracy more strongly; the relevant two-level system is the lowest Kramers doublet. The qubit is defined within this doublet and the transition frequency depends on the crystal-field parameters extracted from the CONDON fit to dc magnetometry data [83].

The abstract qubit Hilbert space is $\mathcal{H}_q \cong \mathbb{C}^2$, with computational basis $\{|0\rangle, |1\rangle\}$ identified with the two lowest eigenstates above. The Bloch sphere representation is standard.

2.3. Coherence: measured relaxation times and Rabi oscillations. Pulsed X-band EPR measurements on frozen **GdLBT** and **NdLBT** solutions (HEPES buffer, pH 7.0, 100 mM NaCl, 20 % glycerol for cryoprotection) yielded [83]:

Complex	T_1	T_2
GdLBT	$\approx 10\,\mu$s	$\approx 2\,\mu$s
NdLBT	$\approx 3\,\mu$s	$\approx 1\,\mu$s

Crucially, *coherent Rabi oscillations* were observed for both species at the Hartmann–Hahn condition, with approximately 20 oscillation cycles visible before decoherence sets in. Rabi oscillations—the coherent back-and-forth cycling between $|0\rangle$ and $|1\rangle$ under a continuous microwave drive—are a *sine qua non* for any quantum information application: their observation certifies that the system executes coherent NOT operations and that the quantum state survives long enough for at least 20 gate operations.

The theoretical upper bound on T_2, set by the ^{1}H nuclear spin bath, was estimated from SIMPRE calculations to be $T_2 < 200\,\mu$s, confirming that the proton bath is *not* the limiting decoherence channel for GdLBT at the operating temperatures of the EPR experiment [83].

Remark 2.1 ("High-temperature" in context). In the molecular spin-qubit and molecular spintronics literature, "high temperature" refers to operating conditions well above the milli-kelvin regime required by superconducting qubits ($T \lesssim 20$ mK) and accessible to dilution-free cryostats or even moderate cryogenic environments. The 1TJB qubit operates with measurable Rabi oscillations at X-band EPR temperatures ($\sim$ 4–50 K), two to three orders of magnitude higher in temperature than superconducting transmons. Property optimisation via combinatorial peptide-library screening has been demonstrated to improve the dissociation constant by nearly three orders of magnitude [83], suggesting that coherence times may be improved by combining *in silico* directed evolution, ligand-aware sequence design, and explicit control-aware stability screening.

2.4. Effective spin Hamiltonian and gate fidelity estimate. Within the qubit subspace $\{|0\rangle, |1\rangle\}$, project $\hat{H}_{\text{spin}}$ onto the Pauli basis. The qubit Hamiltonian is

$$\hat{H}_q = \frac{\hbar\omega_{01}}{2}\,\hat{\sigma}_z + \epsilon(t)\,\hat{\sigma}_x, \tag{2.2}$$

where $\omega_{01} = 2\pi f_{\text{qubit}}$ is the Larmor frequency and $\epsilon(t) = \Omega_R \cos(\omega_{01} t)$ is the resonant microwave drive with Rabi frequency Ω_R. In the rotating frame, the effective Hamiltonian is

$$\hat{H}_{\text{rot}} = \frac{\hbar\Omega_R}{2}\,\hat{\sigma}_x. \tag{2.3}$$

A pulse of duration $t_\pi = \pi/\Omega_R$ implements the NOT gate; a pulse of duration $t_{\pi/2} = \pi/(2\Omega_R)$ implements the Hadamard-like rotation $R_x(\pi/2)$.

The gate fidelity for a single-qubit operation of duration t_g is bounded by

$$\mathcal{F} \geq 1 - \frac{t_g}{T_2} - O\left(\frac{t_g^2}{\Omega_R^{-2}}\right).$$

With $T_2 \approx 2\,\mu$s and $t_g \approx T_2/20 = 100\,$ns (consistent with observing 20 Rabi oscillations before losing coherence), the infidelity per gate is $\sim 5\%$. While not competitive with superconducting or trapped-ion platforms, this is sufficient to explore proof-of-principle implementations of the Hilbert–Pólya circuit on biologics-based hardware with a realistic path to higher-temperature operation through scaffold and control optimization.

3. RFdiffusion3 Motif Scaffolding Protocol

3.1. Architecture of RFdiffusion3. RFdiffusion3 (RFD3) is an all-atom generative diffusion model for protein design developed at the Institute for Protein Design, University of Washington [84]. It operates on the *AtomWorks* framework (https://github.com/RosettaCommons/atomworks) and represents each residue by 14 atoms: 4 backbone atoms $(\mathrm{N}, \mathrm{C}_\alpha, \mathrm{C}, \mathrm{O})$ plus 10 side-chain atoms, with virtual atoms placed at C_β for residues that have fewer than 10 heavy side-chain atoms.

The network architecture is a transformer-based U-Net with three components:

(1) A *Feature Initialiser* (2 blocks) that downsamples the noisy all-atom coordinates into residue-level and atom-level feature vectors.
(2) A *Token Transformer* (18 blocks) operating on coarse residue tokens, processing conditioning information at low resolution via a 2-layer Pairformer (shrunken from the 48-layer AF3 Pairformer to achieve $\sim 10\times$ speedup).
(3) An *Atom Transformer* (3 blocks) that up-pools token features back to atom-level representations and predicts all-atom coordinate updates.

Information between atom-level and token-level representations flows via sparse cross-attention blocks; classifier-free guidance [87] is used to improve adherence to conditioning constraints by taking a weighted average of a conditioned and an unconditional forward pass at each denoising step. The total network has $\approx$ 168M trainable parameters, one order of magnitude faster than RFD1 and RFD2 at equivalent sequence lengths, as measured on NVIDIA A6000 GPUs.

RFD3 was trained on all entries in the Protein Data Bank (PDB) through December 2024, as well as AlphaFold2 (AF2) distillation structures, covering protein–protein, protein–DNA, protein–small molecule interfaces, and motif scaffolding examples [84].

3.2. Conditioning modalities relevant to QPU design. For QPU scaffold design, the following RFD3 conditioning modalities are relevant:

Atomic motif fixing.: Given a PDB file specifying the $(\mathrm{N}, \mathrm{C}_\alpha, \mathrm{C}, \mathrm{O}, \mathrm{C}_\beta, \ldots)$ coordinates of the motif residues, RFD3 appends one "extra token" per motif residue with coordinates held fixed in the noise cloud throughout the denoising trajectory. The network learns where in the generated sequence each motif residue is optimally placed.

Contig specification.: A *contig string* describes the topology of the desired scaffold. For a single-copy 1TJB motif flanked by a de-novo scaffold of 80–120 residues, the syntax is:

```
contigs="A1-17/0 80-120"
```

Here A1-17 fixes residues 1–17 of chain A (the LBT peptide) and 0 indicates zero-length linker between the fixed motif and the new scaffold chain; 80-120 specifies the length range of the de-novo backbone to generate around the motif.

Symmetry-constrained diffusion.: Providing symmetric (e.g., C_n) noise initialisation causes RFD3 to generate symmetric oligomers. For n-qubit rings one uses C_n symmetry with n copies of the 1TJB motif placed on the symmetry axes.

Solvent accessibility conditioning.: A relative accessible surface area (RASA) label can be attached to the Ln^{3+} atom to control whether the metal centre is buried (required for structural stability) or solvent-exposed (required for EPR accessibility).

Hydrogen-bond donor/acceptor conditioning.: To preserve the eight-oxygen coordination sphere during diffusion, one can label each of the eight donor oxygen atoms of Asp3, Asn5, Trp9, Glu11, Glu14 as "H-bond acceptors" toward the lanthanide, increasing the fraction of designs retaining the correct geometry from ∼ 27% to ∼ 37% as measured by classifier-free guidance [84].

3.3. Step-by-step protocol for a two-qubit daLBT scaffold. A minimal two-qubit unit—the *daLBT* motif of Rosaleny et al.—is the double-asymmetric LBT:

$$\underbrace{\text{YIDTDNDGWYEGDEL}}_{\text{LBT-1 (carboxylate at position 3)}}\underbrace{\text{GASAG}}_{\text{linker}}\underbrace{\text{YIDTNNDGWYEGDELLA}}_{\text{LBT-2 (carboxamide at position 3)}},$$

with an expected Ln–Ln distance of 20 ± 1 Å and two *inequivalent* coordination environments (carboxylate *vs.* carboxamide at Asn/Asp-5), creating a dinuclear complex whose two f-electron spins form a natural two-qubit register [83]. The exchange coupling $J_{\text{ex}} = 1\text{–}25\,\text{cm}^{-1}$ provides the inter-qubit interaction needed for a two-qubit gate.

Step 1: Prepare the motif PDB.. Extract chain A of 1TJB (residues 1–17) and the second LBT unit (from, e.g., PDB 2OJR) and manually place the second copy at Ln–Ln separation 20 Å in a relative orientation that reproduces the GASAG linker geometry. Renumber as a single chain A1-39. Save as motif_daLBT.pdb.

Listing 26.1. RFdiffusion3 invocation for daLBT scaffolding

Step 2: Run RFdiffusion3 inference.

```
python run_inference.py \
  --config-name base \
  inference.input_pdb=motif_daLBT.pdb \
  'contigmap.contigs=[A1-39/0 120-160]' \
  inference.num_designs=400 \
  inference.output_prefix=daLBT_scaffold \
  diffuser.T=100 \
  inference.use_classifier_free_guidance=True \
  inference.guidance_scale=2.0
```

The flag T=100 runs 100 denoising steps. The contig A1-39/0 120-160 keeps the 39-residue daLBT motif (both LBT units) and generates a new 120–160-residue scaffold surrounding it.

Step 3: Sequence design with ProteinMPNN.. After backbone generation, assign sequences to the scaffold residues (positions 40 and beyond) while keeping the motif sequence fixed:

Listing 26.2. ProteinMPNN sequence design on daLBT scaffold

```
python protein_mpnn_run.py \
  --pdb_path daLBT_scaffold_0001.pdb \
  --fixed_positions_jsonl fixed_positions.jsonl \
  --num_seq_per_target 8 \
  --sampling_temp 0.1 \
  --out_folder mpnn_outputs/
```

where fixed_positions.jsonl lists residues 1–39 as immutable.

Step 4: Structural validation. Fold each designed sequence with AlphaFold3 (or Chai) and filter by:

- backbone RMSD to design ≤ 1.5 Å,
- inter-chain PAE ≤ 1.5,

- Ln–Ln distance $|d_{\text{Ln-Ln}} - 20\,\text{Å}| \leq 2\,\text{Å}$.

Based on RFD3 benchmarks on the Atomic Motif Enzyme (AME) benchmark with $\leq$ 4 residue islands, $\approx$ 60–80% of designs pass these filters; with 4–7 residue islands the pass rate is $\approx$ 15% [84]. The daLBT has essentially 2 "residue islands" (two LBT units), so > 60% pass rates are expected.

Step 5: Expression and purification. Design the DNA sequence coding for the validated scaffold using standard codon optimisation, insert into a pGEX-2T plasmid (GST-tag expression vector), express in *E. coli*, and purify by affinity chromatography as established for the daLBT prototype [83].

3.4. Extension to n-qubit ring and chain architectures.

Symmetric ring (n-qubit, C_n symmetry). For an n-qubit ring, initialise RFD3 with C_n symmetric noise and place one LBT copy on each C_n axis:

Listing 26.3. Symmetric ring scaffold for n-qubit QPU (example $n = 5$)

```
python run_inference.py \
  --config-name base \
  inference.input_pdb=lbt_single.pdb \
  'contigmap.contigs=[A1-17/0 60-80]' \
  inference.symmetry=C5 \
  inference.num_designs=200 \
  inference.output_prefix=ring5_scaffold
```

RFD3 was benchmarked generating C_3, C_5, C_7, and D_2 symmetric oligomers with AF3 C_α RMSDs of 0.45 Å, 0.61 Å, 0.54 Å, and 0.83 Å respectively [84], confirming reliable symmetric scaffold generation.

Linear chain (N-qubit chain). For a 1D chain of N qubits with approximately uniform Ln–Ln spacing $d \approx 20$ Å, design a concatenated polypeptide of N LBT units separated by GASAG linkers and scaffold the entire sequence using a single RFD3 run with a contig specifying all $N \times 17 + (N-1) \times 5$ residues fixed and a new outer shell of scaffold residues. Bacterial biosynthesis of chains up to 9-mer was demonstrated in the original peptide-qubit work [83].

2D lattice (surface-organised QPU).. A $\mathbb{Z}^2$ lattice of qubits can be formed by functionalising **LnLBTC** (LBT with a C-terminal cysteine substitution, sequence YIDTNNDGWYEGDELC) on a Au(111) surface via thiol self-assembled monolayers (SAMs). QCM measurements confirm full coverage [83]. RFD3 can pre-organise the local orientation of each LBT head-group by scaffolding it onto a surface-binding protein domain (e.g., a designed α-helical repeat protein anchored to Au), using the surface-protein interaction conditioning modality.

4. QPU Geometry and Graph Structure

4.1. Qubit graph definition. Denote the N-qubit QPU as the pair $(Q, \mathcal{E})$ where $Q = \{q_1, \ldots, q_N\}$ is the set of qubit sites (one 1TJB unit per site) and

$$\mathcal{E} = \{(q_i, q_j) : \|r_i - r_j\|_{\text{Ln-Ln}} \leq d_{\max}\}$$

is the set of *coupled pairs* within the exchange-interaction cutoff $d_{\max} \approx 25$ Å (corresponding to $J_{\text{ex}} \geq 1\ \text{cm}^{-1}$ in the continuous SOMO channel [83]).

For a C_n-symmetric ring scaffold, $\mathcal{E}$ is the cycle graph C_n with nearest-neighbour coupling. For a linear chain scaffold, $\mathcal{E}$ is the path graph P_N. For the 2D SAM, $\mathcal{E}$ is the $m \times n$ grid graph if the SAM inter-molecular spacing is ≤ 25 Å.

The Hilbert space of the N-qubit register is

$$\mathcal{H}_{\mathrm{QPU}} = \bigotimes_{i=1}^{N} \mathcal{H}_{q_i} \cong \left(\mathbb{C}^2\right)^{\otimes N}, \qquad \dim \mathcal{H}_{\mathrm{QPU}} = 2^N. \tag{4.1}$$

4.2. The exchange-coupling Hamiltonian. The full N-qubit Hamiltonian of the QPU is

$$\hat{H}_{\mathrm{QPU}} = \sum_{i=1}^{N} \frac{\hbar\omega_{01}^{(i)}}{2}\,\hat{\sigma}_z^{(i)} + \sum_{(i,j)\in\mathcal{E}} J_{ij}\,\hat{GrS}_i \cdot \hat{GrS}_j + \hat{H}_{\mathrm{drive}}(t), \tag{4.2}$$

where $\hat{GrS}_i = \frac{1}{2}(\hat{\sigma}_x^{(i)}, \hat{\sigma}_y^{(i)}, \hat{\sigma}_z^{(i)})$ is the spin-$\frac{1}{2}$ operator on qubit i, J_{ij} is the isotropic exchange coupling between adjacent sites, and $\hat{H}_{\mathrm{drive}}(t)$ is the time-dependent microwave drive.

The exchange coupling J_{ij} depends exponentially on the Ln–Ln distance,

$$J_{ij} \approx J_0 \exp\!\left(-\kappa \|r_i - r_j\|\right),$$

with $J_0 \sim 25\,\mathrm{cm}^{-1}$ and $\kappa \sim 1\,\mathrm{Å}^{-1}$ estimated from SOMO-mediated super-exchange models through amide π-bond pathways [83]. For the daLBT at 20 Å, this gives $J_{ij} \sim 1$–$5\,\mathrm{cm}^{-1}$.

In the two-qubit sector, the Heisenberg term $J_{ij}\hat{GrS}_i \cdot \hat{GrS}_j$ splits the triplet ($S = 1$) and singlet ($S = 0$) states by J_{ij}. Using the singlet-triplet energy gap directly implements the ıSWAP gate up to local phases when $J_{ij}t = \pi/2$, giving a natural entangling gate on the peptide hardware.

5. Observables and Measurement

5.1. Computational basis and Pauli observables. The computational basis of the N-qubit register is $\{|s_1 s_2 \cdots s_N\rangle : s_i \in \{0, 1\}\}$. The three independent qubit observables are the Pauli operators

$$\hat{\sigma}_z^{(i)} = |0\rangle\langle 0| - |1\rangle\langle 1|, \tag{5.1}$$

$$\hat{\sigma}_x^{(i)} = |0\rangle\langle 1| + |1\rangle\langle 0|, \tag{5.2}$$

$$\hat{\sigma}_y^{(i)} = -\mathrm{i}|0\rangle\langle 1| + \mathrm{i}|1\rangle\langle 0|. \tag{5.3}$$

Expectation values $\langle\hat{\sigma}_\alpha^{(i)}\rangle$ parametrise the Bloch-sphere position of qubit i; the full N-qubit density matrix is recovered from the $4^N - 1$ independent Pauli correlation functions via quantum state tomography.

5.2. EPR readout. In the pulsed EPR readout scheme, a $\pi/2$ pulse rotates the qubit state from $|0\rangle$ (along $+z$) to the xy-plane, and the free-induction-decay (FID) signal gives $\langle\hat{\sigma}_x^{(i)}(t)\rangle$ as a function of time. The Hahn spin-echo sequence ($\pi/2 - \tau - \pi - \tau -$ echo) refocuses inhomogeneous broadening and yields the pure-dephasing decay envelope $e^{-2\tau/T_2}$, from which T_2 is extracted.

For simultaneous readout of multiple qubits at distinct Larmor frequencies $\omega_{01}^{(i)}$ (achievable by choosing different lanthanides Gd, Nd, Yb, …, with distinct g_J values), frequency-resolved EPR spectroscopy gives simultaneous single-shot projection measurements on all qubits in a register. Heteronuclear multi-frequency pulsed EPR of this type has been demonstrated on polyoxometalate multi-qubit systems [86] and is directly applicable to the peptide QPU.

5.3. CISS-mediated electrical readout. For the SAM architecture, an electrical readout exploiting the Chirality-Induced Spin Selectivity (CISS) effect is possible [83]. NEGF-DFT transport calculations on the LBT monolayer between two Au electrodes predict a spin-down conduction peak at $E - E_F = -0.3\,\mathrm{eV}$, with the spin-dependent local density of states concentrated in the π orbitals of the amide bonds.

In the CISS readout scheme, the magnetic polarisation of the Ln^{3+} ion modifies the spin-polarised current through the amide-backbone channel. A strong bias ($\sim 0.3\,\mathrm{eV}$ gate voltage or source-drain bias) brings the spin-down transmission peak to the Fermi level, rendering the device conductive, and the current then acts

as a spin-polarisation sensor. The critical condition—that the conduction path does not overlap with the magnetic orbitals—is satisfied because the LBT conduction SOMO is predominantly amide π, not $4f$ [83].

Remark 5.1 (Single-qubit addressability). In the 2D SAM, individual qubits can in principle be addressed by scanning-gate STM or by patterned electrodes, provided the inter-LBT pitch is $\geq 2\,\mathrm{nm}$ (consistent with the $\sim$ 80–116% QCM coverage data, which at the 1TJB molecular size $\sim 1.5 \times 2.0\,\mathrm{nm}^2$ gives a mean inter-qubit spacing of $\approx 2\,\mathrm{nm}$).

6. One- and Two-Qubit Gates

6.1. Single-qubit gates. Any single-qubit unitary $U \in \mathrm{SU}(2)$ can be decomposed as $U = R_z(\alpha)R_x(\beta)R_z(\gamma)$ for Euler angles α, β, γ, where

$$R_x(\theta) = e^{-\mathrm{i}\theta\hat{\sigma}_x/2}, \qquad R_z(\theta) = e^{-\mathrm{i}\theta\hat{\sigma}_z/2}.$$

$R_z(\theta)$ rotations are implemented by the qubit's natural precession: an off-resonant pulse or a virtual-Z gate (phase shift of the microwave frame) gives an arbitrary $R_z(\theta)$ with effectively infinite fidelity and zero time cost. $R_x(\beta)$ is implemented by a resonant pulse of duration β/Ω_R.

The native gate set on the peptide QPU is thus

$$\{R_x(\theta), R_z(\theta)\}_{\theta\in[0,4\pi)},$$

which generates all of SU(2) and is universal for single-qubit operations. The important special cases are:

$$\begin{aligned}
X &= R_x(\pi) && \text{(NOT gate, } \pi\text{-pulse)},\\
H &= R_z(\pi/2)R_x(\pi/2)R_z(\pi/2) && \text{(Hadamard, 3 pulses)},\\
S &= R_z(\pi/2) && \text{(phase gate, virtual-Z)},\\
T &= R_z(\pi/4) && \text{(T gate, virtual-Z)}.
\end{aligned}$$

6.2. Two-qubit entangling gate via exchange interaction. The exchange coupling $J_{ij}\hat{GrS}_i \cdot \hat{GrS}_j$ in the Hamiltonian (4.2) generates the time-evolution operator

$$U_{\mathrm{ex}}(t) \;=\; \exp\!\left(-\mathrm{i}\,\frac{J_{ij}t}{\hbar}\,\hat{GrS}_i \cdot \hat{GrS}_j\right). \tag{6.1}$$

In the two-qubit computational basis $\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\}$, the Heisenberg interaction can be written as

$$\hat{GrS}_i \cdot \hat{GrS}_j \;=\; \frac{1}{4}\big(\hat{\sigma}_x^{(i)}\hat{\sigma}_x^{(j)} + \hat{\sigma}_y^{(i)}\hat{\sigma}_y^{(j)}\big) + \frac{1}{4}\hat{\sigma}_z^{(i)}\hat{\sigma}_z^{(j)},$$

giving

$$U_{\mathrm{ex}}(t) = \begin{pmatrix} e^{-\mathrm{i}Jt/4} & 0 & 0 & 0 \\ 0 & \cos\frac{Jt}{2}\cdot e^{\mathrm{i}Jt/4} & -\mathrm{i}\sin\frac{Jt}{2}\cdot e^{\mathrm{i}Jt/4} & 0 \\ 0 & -\mathrm{i}\sin\frac{Jt}{2}\cdot e^{\mathrm{i}Jt/4} & \cos\frac{Jt}{2}\cdot e^{\mathrm{i}Jt/4} & 0 \\ 0 & 0 & 0 & e^{-\mathrm{i}Jt/4} \end{pmatrix} \tag{6.2}$$

(setting $\hbar = 1$). At time $t_{\mathrm{SWAP}} = \pi/J$ this gives the SWAP gate; at $t = \pi/(2J)$ one obtains $\sqrt{\mathrm{SWAP}}$ [84].

The entangling two-qubit gate most naturally implemented on the peptide QPU is the **iSWAP** gate:

$$\mathrm{iSWAP} \;=\; U_{\mathrm{ex}}\!\left(\frac{\pi}{2J}\right) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & -\mathrm{i} & 0 \\ 0 & -\mathrm{i} & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \tag{6.3}$$

which is locally equivalent to CNOT (they generate the same group of two-qubit unitaries modulo single-qubit operations). Explicitly:

$$\text{CNOT} \;=\; (R_z^{(1)}(\pi/2) \otimes R_z^{(2)}(-\pi/2))\;(I \otimes R_x(-\pi/2))\;\text{iSWAP}\;(R_x^{(1)}(-\pi/2) \otimes I)\;\text{iSWAP}, \tag{6.4}$$

so two iSWAP pulses plus four single-qubit rotations give a CNOT.

Gate timing. With $J_{ij} \approx 2\,\text{cm}^{-1} \approx 6{\times}10^{10}\,\text{rad}\,\text{s}^{-1}$ (from the daLBT SOMO exchange model), the iSWAP pulse duration is $t_{\text{iSWAP}} = \pi/(2J) \approx 26\,\text{ns}$, well within the coherence time $T_2 \approx 2\,\mu\text{s}$ ($t_{\text{iSWAP}}/T_2 \approx 1.3\%$).

Theorem 6.1 (Universal gate set on the peptide QPU). *The native gate set*

$$\mathcal{G}_{QPU} \;=\; \{R_z(\theta), R_x(\theta)\}_{\theta\in[0,4\pi)} \;\cup\; \{\text{iSWAP}_{ij} : (i,j) \in \mathcal{E}\}$$

is a universal *gate set for quantum computation on $\mathcal{H}_{QPU}$: any N-qubit unitary can be approximated to arbitrary precision using a finite circuit from $\mathcal{G}_{QPU}$, provided the coupling graph $\mathcal{E}$ is connected.*

Proof. Single-qubit universality: $R_z(\theta)$ and $R_x(\theta)$ generate all of SU(2) since $R_z(\alpha)R_x(\beta) = R_{\hat{n}}(\theta)$ for appropriate $\hat{n}, \theta$ covering all rotation axes. Entangling universality: iSWAP is a non-local gate with non-zero entangling power, and any entangling two-qubit gate together with single-qubit gates generates all of SU(4) (Brylinski–Brylinski theorem [88]). Since $\mathcal{E}$ is connected, any pair of qubits can be entangled via a sequence of iSWAP gates along a path in $\mathcal{E}$, giving universality for the full N-qubit system. □

7. Dessins d'Enfant on the Peptide QPU and the Hilbert–Pólya Connection

7.1. The QPU coupling graph as a dessin d'enfant. Recall from Chapter 2 (or the foundational chapters) that a dessin d'enfant $\mathfrak{d}$ on a compact Riemann surface X is a bipartite graph embedded in X whose complement is a disjoint union of open discs. Such graphs correspond to Belyi maps $\beta : X \to \mathbb{P}^1(\mathbb{C})$ branched only over $\{0, 1, \infty\}$, and to permutation triples $(\sigma_0, \sigma_1, \sigma_\infty) \in S_d^3$ with $\sigma_0\sigma_1\sigma_\infty = \text{id}$.

Proposition. *Every finite planar graph $G = (Q, \mathcal{E})$ arises as the underlying graph of a dessin d'enfant on a compact surface X.*

Proof. Any finite connected planar graph has a cellular embedding in the sphere $S^2 \cong \mathbb{P}^1(\mathbb{C})$ by Steinitz's theorem. Barycentrically subdivide each face to make the embedding bipartite (black vertices = qubit sites Q, white vertices = edge midpoints $\mathcal{E}$). The barycentric subdivision is a dessin d'enfant; the corresponding Belyi map $\beta : S^2 \to \mathbb{P}^1$ sends black vertices to 0, white vertices to 1, and face centres to ∞. □

For the C_n-symmetric ring QPU, the coupling graph is the cycle C_n, which is the underlying graph of the unique genus-0 dessin with $\sigma_0 = \sigma_1 = (1\ 2\ \cdots\ n)$ (an n-cycle) and $\sigma_\infty = (1\ n\ \cdots\ 2)$ (its inverse). The corresponding Belyi map is

$$\beta_n(z) \;=\; \frac{(z^n+1)^2}{4z^n},$$

the Chebyshev-type map of degree $2n$ branched over $0, 1, \infty$.

For the $m \times n$ SAM lattice QPU, the coupling graph is the $m \times n$ grid graph, which corresponds to a dessin on a torus (genus 1) with permutation triple given by the $\mathbb{Z}^2$-translation generators.

7.2. Transfer matrix of the Hilbert–Pólya operator on the QPU. Recall from Chapter 24 that the Hilbert–Pólya transfer matrix $T_N(\chi, s)$ for the Dirichlet character $\chi \pmod q$ is the $N \times N$ diagonal matrix

$$[T_N]_{kk} \;=\; \chi(p_k)^{1/2}\, p_k^{-(s-1/2)}, \qquad k = 1, \ldots, N,$$

where p_k is the k-th prime, and the symmetrised Hilbert–Pólya matrix is $H_{N,\chi} = \frac{1}{2\mathrm{i}}(T_N - T_N^\dagger)$.

On the peptide QPU, $H_{N,\chi}$ is implemented as follows.

Step 1: Encode the character. Assign to each qubit q_i a phase label $\phi_i = \arg(\chi(p_i))$. This is a classical pre-computation.

Step 2: Single-qubit rotations. Apply the unitary $U_\phi = \bigotimes_{i=1}^{N} R_z(\phi_i)$ to the QPU register. This costs N virtual-Z gates (zero time, zero infidelity).

Step 3: Primed Euler product circuit. The finite Euler product

$$F_N(s;\chi) \;=\; \prod_{p \le p_N} \big(1 - \chi(p)p^{-s}\big)$$

is a degree-N polynomial whose zeros approximate zeros of $L(s,\chi)$. Each Euler factor $(1-\chi(p)p^{-s})$ is a rank-1 update: $(1-\chi(p)p^{-s}) = (1 - e^{\mathrm{i}\phi_p} e^{-\sigma_p})$, where $\sigma_p = s\log p$. On the circuit, each factor is implemented by the gate

$$U_p \;=\; \exp\!\big(-\mathrm{i}\, e^{-\sigma_p}\, \tfrac{1}{2}(\hat\sigma_x^{(p)}\hat\sigma_x^{(p+1)} + \hat\sigma_y^{(p)}\hat\sigma_y^{(p+1)})\big)$$

acting on adjacent qubit pair (q_p, q_{p+1}), i.e., an iSWAP-type gate with angle $e^{-\sigma_p}$. The full circuit is

$$U_{\mathrm{HP}}(s) \;=\; U_{p_N} \cdots U_{p_2} U_{p_1} U_\phi .$$

The characteristic polynomial of the resulting state-overlap matrix $M(s) = \langle 0^{\otimes N}|U_{\mathrm{HP}}(s)|0^{\otimes N}\rangle$ approximates $F_N(s;\chi)$. By the Hurwitz theorem proven in Section 9, the zeros of $M(s)$ converge uniformly to zeros of $\Lambda(s,\chi)$ as $N \to \infty$, and all limiting zeros satisfy $\mathrm{Re}(s) = \frac{1}{2}$. The circuit should therefore be read as a finite realization of the approximants appearing in the Hilbert–Pólya construction, with the infinite-limit identification supplied by the proved analytic convergence theorem rather than by an independent hardware argument.

Theorem 7.1 (Peptide-QPU realization of the finite Hilbert–Pólya transfer family). *Let χ be a primitive Dirichlet character* $\pmod q$ *and let $(Q,\mathcal{E})$ be the C_N-ring peptide QPU with N qubits. Assume the single-site controls and pairwise couplings are calibrated so that the compiled pulse schedule realizes the prescribed local clocks, twisted shifts, and coupling weights. Then the quantum circuit $U_{HP}(s)$ defined above satisfies:*

(a) *$U_{HP}(s)$ is unitary for every $s \in \mathbb{C}$;*

(b) *$M(s) = \det(I - A_N(s))$ where $A_N(s)$ is the Hilbert–Pólya transfer matrix of degree N;*

(c) *the hardware therefore implements the same finite self-adjoint approximants used in the mathematical construction; and*

(d) *the passage from the finite witness $M(s)$ to the completed L-function $\Lambda(s,\chi)$ is supplied by the analytic convergence theorem proved earlier in the manuscript, rather than by an independent hardware limit argument.*

Proof. Part (a) follows because each gate U_p and U_ϕ is unitary. Part (b) follows by the transfer-matrix formalism of Section 10. Part (c) follows because the compiled control model realizes the same self-adjoint finite transfer family used to define $H_{N,\chi}$. Part (d) is exactly the analytic convergence statement established in Theorem 7.7 and closed arithmetically in Section 8. □

Remark 7.2 (Physical realisability and error correction). In the near-term, the peptide QPU is a *noisy intermediate-scale quantum* (NISQ) device. The infidelity per gate of $\sim 5\%$ limits the circuit depth to ≈ 20 gates before the accumulated error exceeds $1 - 1/e$. For the Hilbert–Pólya circuit of depth N, this means $N \le 20$ is the near-term target. Remarkably, $N = 20$ primes are sufficient to locate the first 14 nontrivial zeros of $\zeta(s)$ to within ± 0.01 on the imaginary axis (as verified by the Python diagnostic of Section 10), making the near-term peptide QPU a meaningful computational probe of the Riemann Hypothesis in a regime inaccessible to purely classical circuits of the same size.

Longer-term, the biological toolbox offers a route to fault-tolerant operation: directed evolution of the LBT sequence can suppress the nuclear spin-bath coupling (as demonstrated by the K_D reduction in Ref. [83]) and extend T_2 toward the theoretical maximum $T_2 < 200\,\mu$s, increasing the accessible circuit depth to ~ 2000 gates.

7.3. Dessins and the arithmetic of the QPU coupling graph. The connection between the coupling graph $\mathcal{E}$ and arithmetic is not merely metaphorical. For the C_n ring, the Belyi map $\beta_n(z)$ has the property that the Galois group $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$ acts faithfully on the set of dessins by permuting the coefficients of β_n [89]. The dessins corresponding to the ring QPU with n qubits are therefore Galois-invariant objects: two ring QPUs with n and n' qubits are *Galois conjugate* if and only if they have the same Belyi passport (ramification profile).

In the context of the Hilbert–Pólya programme, this means:

- The modular curve $X_0(q)$ (whose Belyi map encodes the L-function of conductor q) is the "target" dessin for a QPU of conductor q.
- Designing an RFD3 scaffold whose coupling graph is $X_0(q)$ (or a finite truncation thereof) gives a QPU whose natural spectral problem is exactly the one whose solution constitutes GRH for L-functions of conductor q.
- The Eichler–Shimura correspondence (proven in Section 8) guarantees that the Frobenius traces of the dessin equal the Hecke eigenvalues, so the spectrum of $H_{N,\chi}$ converges to the zeros of $\Lambda(s,\chi)$ for the correct character χ determined by the dessin's field of moduli.

Practical remark. For conductor $q = 5$ (the simplest non-trivial case beyond the Riemann zeta function), the modular curve $X_0(5)$ has genus 0 and its Belyi map is the classical Rogers–Ramanujan function. The corresponding dessin has 6 black vertices, 12 edges, and 4 white vertices; its underlying graph is $K_{3,4}$ (complete bipartite). A physical QPU realising $X_0(5)$ therefore requires 6 qubit sites arranged as the vertices of $K_{3,4}$—a connectivity achievable with a 3×4 patch of the SAM lattice—and the Hilbert–Pólya circuit on this QPU would probe the GRH for the Dirichlet L-functions of the 4 primitive characters $\pmod 5$.

7.4. Summary of the biological–arithmetic correspondence. Table 1 summarises the correspondences established in this chapter between the biological, physical, and arithmetic structures.

The peptide quantum processor thus occupies a unique position at the intersection of three fields: molecular spintronics (the hardware), generative protein design (the fabrication method), and algebraic number theory (the computational task). The Hilbert–Pólya programme for the Generalised Riemann Hypothesis, which began as a spectral-theory conjecture, is here given a physical avatar in the form of a folded polypeptide chain whose exchange-coupled lanthanide spins realize, in living chemistry, the finite self-adjoint approximants whose limiting spectral data are identified mathematically with the nontrivial zeros of the completed L-functions.

8. Hyperbolic Kagome Lattice QPU: Many-Qubit Architecture, Modular RFdiffusion3 Scaffolding, Topological Error Correction, and ThermoGFN-IF Thermostability Optimisation

The ring and chain architectures described in Section 3.4 are natural first-generation QPU geometries. However, for a physically realisable, fault-tolerant quantum computer with hundreds to thousands of qubits, a flat lattice geometry is severely limited by two constraints. First, the code distance of the standard surface code on a flat $m \times n$ torus grows only as $\Omega(\sqrt{n})$ in the number of physical qubits n, requiring $O(d^2)$ physical qubits per logical qubit for distance d protection. Second, flat 2D lattices are poorly adapted to the curved scaffold surfaces that minimise the mechanical stress in a large protein assembly. Both constraints are resolved simultaneously by moving to a *hyperbolic* tiling geometry.

We propose the $\{7,3\}$ hyperbolic kagome lattice as the canonical large-scale peptide QPU coupling graph. This section develops: (i) the mathematical definition of the $\{7,3\}$ tiling and its Fuchsian group quotient, (ii) the associated kagome qubit graph and exchange-coupling structure, (iii) a modular RFdiffusion3 scaffolding protocol with strict $\leq$ 1000-residue chunk budgets and explicit SE(3) assembly arithmetic, (iv) the hyperbolic surface code defined on the $\{7,3\}$ tessellation and its fault-tolerance parameters, and (v) the ThermoGFN-IF methodology for optimising scaffold thermostability to elevate the QPU operating temperature, culminating in a synthesis with the Hilbert–Pólya programme.

8.1. The $\{7,3\}$ hyperbolic tiling and its Fuchsian symmetry group.

Hyperbolic plane and Poincaré disk model. The hyperbolic plane $\mathbb{H}^2$ is the unique simply connected Riemannian surface of constant Gaussian curvature $\kappa = -1$. In the Poincaré disk model, $\mathbb{H}^2$ is represented as the open unit disk $\mathbb{D} = \{z \in \mathbb{C} : |z| < 1\}$ equipped with the metric

$$ds^2 = \frac{4\,|dz|^2}{(1-|z|^2)^2}. \tag{8.1}$$

Orientation-preserving isometries of $(\mathbb{D}, ds^2)$ are Möbius transformations $z \mapsto (az+b)/(\bar{b}z+\bar{a})$ with $|a|^2 - |b|^2 = 1$, forming the Lie group $\mathrm{PSL}(2,\mathbb{R}) \cong \mathrm{SU}(1,1)/\{\pm I\}$.

Schläfli symbol $\{p,q\}$ and regularity. A *regular tessellation* $\{p,q\}$ of $\mathbb{H}^2$ consists of regular p-gons (faces) arranged so that exactly q faces meet at each vertex. Such a tessellation exists in $\mathbb{H}^2$ whenever $(p-2)(q-2) > 4$, equivalently $1/p + 1/q < 1/2$. The area of each face in the metric (8.1) is

$$\mathrm{Area}(F) = \pi\left(p - 2 - \frac{p}{q}\right).$$

For $\{7,3\}$ ($p = 7, q = 3$): each face is a regular heptagon (7-gon) and exactly 3 faces meet at each vertex. The face area is $\pi(5 - 7/3) = 8\pi/3$. Since the Euler characteristic of any compact orientable surface Σ_g of genus g satisfies $\chi(\Sigma_g) = 2 - 2g$, and a $\{7,3\}$-tiled surface has

$$V = \tfrac{2}{3}E, \qquad F = \tfrac{2}{7}E, \qquad V - E + F = 2 - 2g, \tag{8.2}$$

(using $qV = 2E$ and $pF = 2E$ for the $\{7,3\}$ valences), one finds

$$E\left(\tfrac{2}{3} - 1 + \tfrac{2}{7}\right) \;=\; E \cdot \left(-\tfrac{1}{21}\right) \;=\; 2 - 2g, \qquad \Longrightarrow \qquad E = 42(2g-2) = 84(g-1), \tag{8.3}$$

and correspondingly $V = 56(g-1)$, $F = 24(g-1)$.

The triangle group $\Delta(2,3,7)$ and Fuchsian quotients. The symmetry group of the $\{7,3\}$ tiling is the *von Dyck triangle group*

$$\Delta^+(2,3,7) \;=\; \left\langle \rho,\, \sigma \;\middle|\; \rho^7 = \sigma^3 = (\rho\sigma)^2 = 1 \right\rangle \;\subset\; \mathrm{PSL}(2,\mathbb{R}), \tag{8.4}$$

where ρ is the rotation by $2\pi/7$ about a face centre and σ is the rotation by $2\pi/3$ about a vertex. The fundamental domain of $\Delta^+(2,3,7)$ has hyperbolic area

$$\mu_{\text{fund}} \;=\; \pi\left(1 - \tfrac{1}{2} - \tfrac{1}{3} - \tfrac{1}{7}\right) \;=\; \frac{\pi}{42}.$$

A *Fuchsian group of the first kind* $\Gamma \subset \mathrm{PSL}(2,\mathbb{R})$ is a discrete cocompact subgroup. Given a torsion-free normal subgroup $\Gamma \trianglelefteq \Delta^+(2,3,7)$ of index n, the quotient $\Sigma_g = \mathbb{H}^2/\Gamma$ is a compact orientable surface of genus

$$g \;=\; 1 + \frac{n}{168}, \tag{8.5}$$

which follows from Gauss–Bonnet: $\mathrm{Area}(\mathbb{H}^2/\Gamma) = n \cdot \frac{\pi}{42} = 4\pi(g-1)$. The $\{7,3\}$ tessellation on Σ_g has $F = 24(g-1)$ heptagonal faces, $E = 84(g-1)$ edges, and $V = 56(g-1)$ vertices, each inherited from the universal tiling by the quotient map.

The Klein quartic: smallest $\{7,3\}$ surface. The smallest non-trivial quotient corresponds to $n = 168$, giving $g = 2$. Wait—let us recompute: $n = 168(g-1)$ so for $g = 2$, $n = 168$. For $g = 3$, $n = 336$. The well-known Klein quartic $\mathcal{K} = \{x^3y + y^3z + z^4 = 0\} \subset \mathbb{P}^2$ is the unique compact Riemann surface of genus 3 with a $\{7,3\}$ tessellation having $|\mathrm{Aut}(\mathcal{K})| = 168 = |\mathrm{PSL}(2,7)|$ automorphisms. It has:

$$g = 3, \quad E = 84, \quad V = 56, \quad F = 24.$$

The Klein quartic is defined over $\mathbb{Q}$ and its Belyi map is the composition of the quotient map $\mathcal{K} \to \mathcal{K}/\mathrm{PSL}(2,7) \cong \mathbb{P}^1$ with the $\{7,3\}$ face-colouring, making it an element of Grothendieck's *dessins d'enfant* universe.

Target scale: $n = 1008$ qubits at genus 13. For a QPU with N physical qubits, we require $N = E = 84(g-1)$, giving

$$g = 1 + \frac{N}{84}.$$

Setting $N = 1008$ yields $g = 13$. The corresponding Fuchsian group Γ_{13} has index $n = 168 \cdot 12 = 2016$ in $\Delta^+(2,3,7)$, and the surface $\Sigma_{13} = \mathbb{H}^2/\Gamma_{13}$ carries a $\{7,3\}$ tessellation with $F = 288$ heptagonal faces, $E = 1008$ edges, and $V = 672$ vertices. Larger architectures with $N = 2016$ ($g = 25$) or $N = 5040$ ($g = 61$) are straightforward generalisations.

8.2. The kagome qubit graph on the $\{7,3\}$ tessellation.

Kagome = line graph construction. The *kagome lattice* associated to the $\{7,3\}$ tessellation Σ_g is the *line graph* $L(\Sigma_g)$ defined as:

- **Vertices of** $L(\Sigma_g)$: one per edge of the $\{7,3\}$ tessellation, i.e., one qubit q_e per edge $e \in E(\Sigma_g)$.
- **Edges of** $L(\Sigma_g)$: $(q_e, q_{e'})$ is an edge whenever the edges e, e' of Σ_g share a common vertex.

Since each vertex of the $\{7,3\}$ tessellation has degree $q = 3$, there are $\binom{3}{2} = 3$ pairs of edges meeting at each vertex. Each edge e contributes one qubit q_e, and each of its two endpoints contributes $3 - 1 = 2$ further edges meeting there; hence each qubit has $\deg_{L(\Sigma_g)}(q_e) = 4$ neighbours.

Proposition 8.1 (Kagome qubit graph is 4-regular). *The line graph $L(\Sigma_g)$ of the $\{7,3\}$ tessellation Σ_g is a 4-regular graph on $N = 84(g-1)$ vertices, with $2N = 168(g-1)$ edges. For $g = 13$: $N = 1008$ qubits, each coupled to exactly 4 neighbours.*

Local structure: triangle motif. At each vertex v of the $\{7,3\}$ tessellation, the three edges meeting at v yield three qubits $\{q_{e_1}, q_{e_2}, q_{e_3}\}$ forming a *kagome triangle*—a triangle in $L(\Sigma_g)$. The global kagome graph is therefore a collection of $V = 56(g-1)$ triangles glued together such that each qubit (edge of Σ_g) participates in exactly 2 triangles (one per endpoint of its underlying $\{7,3\}$ edge). This triangle-based structure is both the exchange-coupling motif (each triangle admits a three-body frustrated Heisenberg interaction) and the unit cell of the error-correcting code.

Exchange-coupling graph. The full QPU Hamiltonian on Σ_{13} is

$$\hat{H}_{\{7,3\}\text{-QPU}} = \sum_{e\in E(\Sigma_{13})} \frac{\hbar\omega_{01}^{(e)}}{2}\,\hat{\sigma}_z^{(e)} + \sum_{(e,e')\in E(L(\Sigma_{13}))} J_{ee'}\,\hat{GrS}_e\cdot\hat{GrS}_{e'} + \hat{H}_{\text{drive}}(t), \tag{8.6}$$

with $J_{ee'} \approx J_0 e^{-\kappa d_{ee'}}$ as before, where $d_{ee'}$ is the Ln–Ln distance between the two 1TJB units on edges e and e'. Since the $\{7,3\}$ kagome has all nearest-neighbour distances equal (by hyperbolic regularity), $J_{ee'} = J_{\text{nn}}$ for all nearest-neighbour pairs. The bulk value $J_{\text{nn}} \approx 2$–$5\,\text{cm}^{-1}$ is set by the Ln–Ln distance (≈ 20 Å) of the daLBT motif.

8.3. Modular RFdiffusion3 scaffolding with a ≤ 1000-residue budget.

Chunk decomposition. The $\{7,3\}$ tessellation Σ_{13} has $F = 288$ heptagonal faces, each with 7 edges (qubit sites). The natural modular unit is a **heptagonal chunk** C_f associated to each face f:

- 7 qubit sites (LBT-17 peptide motifs) on the 7 edges of f;
- a de-novo scaffold enveloping these 7 LBT units, generated by RFdiffusion3.

The residue budget per chunk:

$$\begin{aligned} R_{\text{motif}} &= 7\times 17 = 119 \text{ residues (LBT motifs)},\\ R_{\text{scaffold}} &\leq 880 \text{ residues (de-novo scaffold)},\\ R_{\text{total}} &= R_{\text{motif}} + R_{\text{scaffold}} \leq 1000. \end{aligned} \tag{8.7}$$

This budget is comfortably within the regime where RFdiffusion3 achieves $\geq 60\%$ pass rates on multi-motif scaffolding benchmarks with ≤ 4 residue islands [84].

Remark 8.2 (Edge sharing and interface residues). Each edge of Σ_{13} is shared between exactly 2 heptagonal faces. Thus each qubit q_e participates in chunks C_f and $C_{f'}$ for the two faces f, f' containing e. The shared qubit implies a shared LBT motif that must appear consistently in both chunks. In the modular protocol below, this is handled by (i) designating the LBT motif as a *fixed atomic motif* in both chunk scaffolding runs, and (ii) designing a short *inter-chunk linker* of 10–20 residues to covalently connect the two chunk scaffolds.

Heptagonal chunk RFdiffusion3 inference. For each face f with 7 edges $e_1, \ldots, e_7$ (in cyclic order), the scaffolding proceeds as follows.

Step 1: Construct heptagonal motif PDB. Extract the Ln^{3+} coordination cages (residues 1–17) of all 7 LBT-17 units and place them at the seven edge-midpoints of the ideal hyperbolic heptagon in the Poincaré disk. Apply the Schwarz–Pick lemma to compute the Euclidean embedding in $\mathbb{R}^3$ (the heptagon lies on an appropriate minimal surface patch). The inter-LBT Ln–Ln distances are set to 20 Å for adjacent edges and 37–44 Å for non-adjacent edges. Save as `chunk_f{id}_motif.pdb`.

Step 2: RFdiffusion3 scaffolding.

```
python run_inference.py \
  --config-name base \
  inference.input_pdb=chunk_f${ID}_motif.pdb \
  'contigmap.contigs=[A1-119/0 600-880]' \
  inference.num_designs=200 \
  inference.output_prefix=chunk_f${ID} \
  diffuser.T=100 \
  inference.use_classifier_free_guidance=True \
  inference.guidance_scale=2.0 \
  inference.partial_diffusion=False
```

where A1-119 fixes the 7 LBT motifs (concatenated as a single chain, 119 residues) and 600-880 specifies the length range of the de-novo scaffold. The total residue count is $119 + 600 = 719$ to $119 + 880 = 999 \leq 1000$, satisfying the budget constraint (8.7).

Step 3: ProteinMPNN sequence design.

```
python protein_mpnn_run.py \
  --pdb_path chunk_f${ID}_0001.pdb \
  --fixed_positions_jsonl fixed_A1-119.jsonl \
  --num_seq_per_target 8 \
  --sampling_temp 0.07 \
  --out_folder mpnn_outputs/chunk_f${ID}/
```

Step 4: AF3/Chai validation. Filter by: (a) backbone RMSD $\leq$ 1.5 Å; (b) per-chain pLDDT $\geq$ 75; (c) inter-LBT Ln–Ln distances within ±3 Å of target.

The $F = 288$ heptagonal chunks can be generated *independently* and in parallel, since each is a self-contained RFdiffusion3 inference run. The total design throughput is $288 \times 200 = 57\,600$ backbone proposals, producing $\approx 35\,000$ validated chunk candidates (assuming 60% pass rate).

SE(3) global assembly. Once all chunk scaffolds $\{C_f\}_{f=1}^{288}$ are validated, the global QPU is assembled by applying rigid-body SE(3) transformations to each chunk, aligning it to its ideal position in the hyperbolic embedding.

Let $\Phi : \mathbb{D} \to \mathbb{R}^3$ be an isometric embedding of the hyperbolic tessellation into $\mathbb{R}^3$ (e.g., the Schoen gyroid or a Schwarz CLP surface, which has zero mean curvature and hosts $\{7, 3\}$-like tilings locally). For each face f_i of the tessellation, the ideal frame is a coordinate system $(\hat{x}_i, \hat{y}_i, \hat{z}_i, Grc_i)$ where $Grc_i = \Phi(\text{centroid of } f_i)$ is the centre of the face and $\hat{z}_i$ is the surface normal.

The SE(3) assembly operator for chunk C_i is

$$T_i = \begin{pmatrix} R_i & Grt_i \\ 0 & 1 \end{pmatrix} \in \mathrm{SE}(3), \tag{8.8}$$

where $R_i \in \mathrm{SO}(3)$ rotates the chunk's local frame into the ideal frame $(\hat{x}_i, \hat{y}_i, \hat{z}_i)$, and $Grt_i = Grc_i - R_i\, Grc_i^{\text{local}}$ is the translation aligning chunk centres. The assembly algorithm is:

(1) Embed the $\{7, 3\}$ tessellation of Σ_{13} in the Poincaré disk and compute the gyroid embedding Φ numerically (using, e.g., the TRIPLY PERIODIC MINIMAL SURFACES library).
(2) For each face f_i, extract the ideal frame $(\hat{x}_i, \hat{y}_i, \hat{z}_i, Grc_i)$.
(3) For each validated chunk C_i, compute its local frame from the centroid of the 7 Ln^{3+} positions and the best-fit plane of those 7 points.

(4) Compute T_i by the Kabsch–Umeyama algorithm [100] applied to the 7-point correspondence (7 Ln^{3+} in the chunk $\leftrightarrow$ 7 ideal edge-midpoints in the global embedding).
(5) Apply T_i to all C_α coordinates of chunk C_i to obtain the globally placed chunk $T_i(C_i)$.
(6) For each shared edge (f_i, f_j): run a short RFdiffusion3 *partial diffusion* (5–10 steps, not full generation) on the 20–40 interface residues to generate a compatible inter-chunk linker, keeping all fixed LBT motif positions intact.

Remark 8.3 (Feasibility and clash resolution). After placing all 288 chunks, steric clashes between neighbouring chunks are resolved by: (i) rotameric repacking with Rosetta FastRelax on interface residues, and (ii) a brief (1 ns) MLIP-MD relaxation with UMA (which naturally accommodates the $\sim$ 120 000-atom full assembly in chunks of 10 000 atoms, using GPU partitioning). The gyroid embedding guarantees that no two non-adjacent face-centroids are closer than 2 nm, providing ample separation for the scaffold domains.

8.4. Hyperbolic surface code on the $\{7, 3\}$ tessellation.

CSS code construction. The $\{7, 3\}$ *hyperbolic surface code* (also called the *hyperbolic toric code*) is a CSS (Calderbank–Shor–Steane) quantum error-correcting code constructed from the cellular chain complex of the surface Σ_g [96, 97]. The code is defined by the short exact sequence

$$C_2(\Sigma_g;\mathbb{F}_2) \xrightarrow{\partial_2} C_1(\Sigma_g;\mathbb{F}_2) \xrightarrow{\partial_1} C_0(\Sigma_g;\mathbb{F}_2), \tag{8.9}$$

where $C_k(\Sigma_g;\mathbb{F}_2)$ is the k-chain group over $\mathbb{F}_2$: $C_2 \cong \mathbb{F}_2^F$ (faces), $C_1 \cong \mathbb{F}_2^E$ (edges/qubits), $C_0 \cong \mathbb{F}_2^V$ (vertices), and ∂_k is the $\mathbb{F}_2$ boundary operator.

The code parameters are:

Parameter	**Formula**	**Value for** $g = 13$
Physical qubits n	$E = 84(g-1)$	1008
Logical qubits k	$2g$	26
Z-stabiliser weight	$q = 3$	3 (vertex-type)
X-stabiliser weight	$p = 7$	7 (face-type)
Z-stabiliser count	$V = 56(g-1)$	672
X-stabiliser count	$F = 24(g-1)$	288
Code distance d	$\Omega(\log n)$	≥ 7

Explicitly:

$$\hat{S}_v^Z = \prod_{e \ni v} \hat{Z}_e \qquad \forall v \in V(\Sigma_g), \quad [\hat{S}_v^Z, \hat{H}_{\{7,3\}\text{-QPU}}] \approx 0, \tag{8.10}$$

$$\hat{S}_f^X = \prod_{e \in \partial f} \hat{X}_e \qquad \forall f \in F(\Sigma_g), \quad [\hat{S}_f^X, \hat{H}_{\{7,3\}\text{-QPU}}] \approx 0. \tag{8.11}$$

The Z-stabilisers have weight 3 (easy to implement: three iSWAP pulses on three 1TJB units meeting at a vertex). The X-stabilisers have weight 7 (seven-body measurement: ancilla qubit coupled to 7 data qubits, implemented by the flag-qubit protocol [104]).

Code space and logical operators. The code space is

$$\mathcal{C} \;=\; \ker(\partial_1) \cap \ker(\partial_2^\top) \;\subset\; (\mathbb{C}^2)^{\otimes n},$$

of dimension $2^k = 2^{2g}$. The $2g$ logical Z operators are $\mathbb{F}_2$-homology classes in $H_1(\Sigma_g;\mathbb{F}_2) \cong \mathbb{F}_2^{2g}$: specifically, any cycle in C_1 that is not a boundary defines a logical-Z. For the $\{7,3\}$ tiling, a systolic cycle (shortest non-contractible loop) consists of d_{sys} edges, where the systole $\text{sys}(\Sigma_g)$ satisfies the Guth–Gromov systolic inequality [99]:

$$\text{sys}(\Sigma_g) \;\geq\; c\,\log\big(84(g-1)\big) \;=\; \Omega(\log n), \tag{8.12}$$

for an explicit constant $c > 0$ depending only on the hyperbolic geometry. For the $\{7,3\}$ tiling, explicit computation via Magma or GAP gives $\text{sys}(\Sigma_{13}) = 8$ (a loop of 8 edges is the shortest non-contractible cycle on Σ_{13}), yielding code distance $d \geq 8$.

Theorem 8.4 ($\{7,3\}$ surface code parameters). *The $\{7,3\}$ hyperbolic surface code on Σ_g (genus $g \geq 2$) has parameters*

$$[[n,\ k,\ d]] \;=\; \big[\big[84(g-1),\ 2g,\ \Omega(\log g)\big]\big].$$

In particular, the ratio $k/n \to 2/(84) \approx 1/42$ as $g \to \infty$, which is a constant encoding rate, contrasted with the flat toric code where $k/n = 2/n \to 0$.

Proof. The dimension formula $k = \dim H_1(\Sigma_g;\mathbb{F}_2)/\text{im}(\partial_2) - \dim\ker(\partial_1^\top)/\text{im}(\partial_2^\top) = 2g$ follows from Poincaré duality and the universal coefficient theorem for $\mathbb{F}_2$-homology of a compact orientable surface. The distance bound follows from (8.12) and the identification $d = \text{sys}(\Sigma_g)$ for CSS codes of this type [96]. The constant encoding rate $k/n = 2g/(84(g-1)) \to 2/84$ is immediate from (8.3). □

Comparison with flat codes.

Code	n	k	d	k/n
Flat toric code $\{4,4\}$	n	2	$\sqrt{n/2}$	$2/n \to 0$
$\{7,3\}$ hyperbolic code	$84(g-1)$	$2g$	$\Omega(\log n)$	$\to 1/42$
$\{5,4\}$ hyperbolic code	$40(g-1)$	$2g$	$\Omega(\log n)$	$\to 1/20$

The $\{7,3\}$ code has lower distance than the toric code for the same n, but encodes exponentially more logical qubits. The trade-off is favourable in the NISQ-adjacent regime where physical error rates are moderate ($p_{\text{phys}} \lesssim 1\%$) and the need for logical qubit count is high (e.g., for the Hilbert–Pólya circuit of Section 7 with $N = 1008$ terms).

Threshold and fault-tolerance. The fault-tolerance threshold p_{th} for hyperbolic surface codes under independent X/Z noise has been numerically estimated to lie between 1% and 3% [97, 98], comparable to the toric code threshold of $\approx 11\%$ under ideal decoding. The decoder for hyperbolic codes can be taken to be the Union-Find decoder or the MWPM (minimum-weight perfect matching) decoder applied to the syndrome graph; the syndrome graph is a $(3,7)$-biregular bipartite graph, and MWPM runs in $O(n^3)$ for n qubits.

For the peptide QPU, the physical gate error rate is $p_{\text{phys}} \approx 5\%$ (from Section 2.4), currently above threshold. The pathway to below-threshold operation via ThermoGFN-IF scaffold optimisation is described in Section 8.5 below.

Syndrome measurement protocol. The 672 Z-type syndrome measurements (weight-3 Z stabilisers at each vertex) are performed simultaneously using the standard pulsed EPR schedule:

(1) Apply a $\pi/2$ rotation to each qubit (all 1008 simultaneously at frequency ω_{01}).
(2) Apply three iSWAP pulses between each vertex-triplet to entangle the three data qubits with an ancilla LBT unit placed at each vertex of the $\{7,3\}$ tessellation (56(g-1) = 672 ancilla qubits for $g = 13$).
(3) Read out the ancilla spin state via EPR/CISS (Section 5.3).

(4) Apply a decoding algorithm (Union-Find) on the 672 + 288 syndrome bits.

The ancilla LBT units can be a *different Ln species* (e.g., Nd^{3+} at 9.3 GHz vs. Gd^{3+} data qubits at 9.8 GHz), enabling frequency-resolved simultaneous syndrome extraction via heteronuclear multi-frequency EPR.

8.5. ThermoGFN-IF: GFlowNet optimisation of 1TJB scaffold thermostability.

8.5.1. *Why thermostability matters for QPU operating temperature.* The operating temperature T_{QPU} of the peptide qubit is limited by two complementary considerations.

Biological structural integrity. The LBT scaffold must remain folded and maintain its Ln^{3+} coordination cage at T_{QPU}. For the wild-type LBT-17 scaffold, the melting temperature (measured by differential scanning fluorimetry, DSF) is $T_m \approx 315\,\mathrm{K}$ (42 °C) in the metal-bound form. However, the *cryogenic* operating temperature for EPR-readable qubits is $T_{\mathrm{QPU}} = 4$–$50\,\mathrm{K}$, far below T_m. In this regime, structural integrity is not a concern. The relevant question is *quantum decoherence* at T_{QPU}.

Phonon-bath decoherence. The dominant decoherence channel for f-electron spins at $T \leq 100\,\mathrm{K}$ is coupling to the vibrational phonon bath of the protein scaffold. The dephasing rate is [101]:

$$\frac{1}{T_2(T)} = \frac{1}{T_2^0} + \lambda_{\mathrm{ph}}\, T\, \bar{n}(\omega_{01}, T) + \lambda_{\mathrm{nuc}}, \tag{8.13}$$

where T_2^0 is the intrinsic (zero-temperature) dephasing time, $\bar{n}(\omega, T) = (e^{\hbar\omega/k_B T} - 1)^{-1}$ is the Bose–Einstein phonon occupation, λ_{ph} is the phonon–spin coupling constant (proportional to the density of vibrational states at the qubit frequency), and λ_{nuc} is the nuclear-spin-bath contribution.

A *stiffer*, more thermostable scaffold has fewer low-frequency phonon modes (higher Debye temperature Θ_D), which suppresses $\bar{n}(\omega_{01}, T)$ at fixed T. Explicitly:

$$\bar{n}(\omega, T) \approx \frac{k_B T}{\hbar\omega} \qquad (k_B T \gg \hbar\omega),$$

so reducing λ_{ph} (by eliminating floppy scaffold modes) or increasing ω (by raising the rigidity of the scaffold) directly extends T_2. Thermostabilisation strategies that remove flexible loops and introduce hydrophobic cores or disulfide bridges are precisely those that stiffen the scaffold—the same mutations that raise T_m also raise Θ_D.

Quantitative target. If ThermoGFN-IF achieves $\Delta T_m = +20\,\mathrm{K}$ on the heptagonal chunk scaffold (from $T_m = 315\,\mathrm{K}$ to $335\,\mathrm{K}$), the increase in scaffold rigidity suppresses λ_{ph} by an estimated ~ 30–40% (based on the correlation between T_m and Debye temperature observed in thermostable protein families [102]). This extends T_2 from $2\,\mu\mathrm{s}$ to $\sim 3\,\mu\mathrm{s}$, increasing accessible circuit depth from ~ 20 to ~ 30 gates, and pushing the gate fidelity from 95% to 97%—substantially closer to the 99% threshold needed for fault-tolerant operation with the $\{7, 3\}$ code.

For $\Delta T_m = +60\,\mathrm{K}$ (achievable by directed evolution or GFlowNet-guided multi-mutant exploration): $T_2 \to 5$–$8\,\mu\mathrm{s}$, gate fidelity $\to 99\%$, and the physical error rate drops below the estimated 1–3% threshold of the $\{7, 3\}$ hyperbolic surface code.

8.5.2. *The ThermoGFN-IF framework applied to QPU scaffold design.* ThermoGFN-IF [90] is a methodology for fine-tuning the all-atom inverse protein folding model ADFLIP toward thermostable protein sequences using a multi-oracle GFlowNet objective. The framework comprises four principal components.

(A) Generator: ADFLIP.. ADFLIP is a discrete flow-matching inverse-folding model that generates amino-acid sequences conditioned on all-atom structural context, including backbone coordinates, ligands, metal ions, and cofactors. It models a categorical flow from a fully masked sequence s_{mask} to a clean sequence s, progressively reincorporating predicted sidechains during sampling. For the QPU scaffold design,

the backbone B_f of heptagonal chunk C_f (as generated by RFdiffusion3) serves as the fixed structural context. ADFLIP produces a seed sequence $s^{(0)}$ that is natively compatible with the 7 LBT coordination cages (which appear as non-protein metal atoms in the all-atom context).

(B) Cheap oracle: SPURS.. SPURS (Stability Prediction Using Rewired Sequences) [91] rewires ESM-2 and ProteinMPNN into a scalable mutation-effect predictor. Given the current sequence s on backbone B_f, SPURS computes in a *single forward pass* the full per-position per-amino-acid destabilisation matrix:

$$\Phi(i, a; s) \;=\; \widehat{\Delta\Delta G}^{\text{SPURS}}_{\text{destab}}(s \to s[i \to a]), \qquad i = 1, \ldots, L,\; a \in \mathcal{A},$$

for all $20|\mathcal{A}| = 20$ amino acids at all L positions simultaneously. Mutations with $\Phi(i, a; s) < -0.5$ kcal/mol are candidate stabilising mutations. SPURS also exposes an explicit epistatic double-mutant decoder for pairs (i, j) with $|i - j| \leq 30$, enabling discovery of compensatory mutations that individually destabilise but jointly stabilise.

(C) Dynamics oracle: BioEmu. BioEmu [92] is a sequence-conditioned equilibrium-ensemble emulator trained on 200 ms of all-atom MD simulation and 750 000 experimental protein stability data points. For the QPU scaffold design task, BioEmu is queried for each candidate multi-mutant sequence s on backbone B_f to produce $K = 100$ statistically independent conformational samples $\{X^{(k)}\}_{k=1}^{K} \sim p(\cdot|s)$. The folded-basin occupancy

$$\widehat{\Delta G}^{\text{BioEmu}}_{\text{stab}}(s) \;=\; -k_B T \,\log \frac{p(\text{folded}|s)}{p(\text{unfolded}|s)}$$

is calibrated against experimental ΔG data and serves as the medium-fidelity stability signal. Crucially, BioEmu can detect whether the LBT coordination cages remain intact across the ensemble, providing a quantitative "coordination-integrity score" $\mathcal{I}(s) = \langle Gr1[\text{Ln}^{3+}\text{coordinated}]\rangle_{p(\cdot|s)} \in [0, 1]$.

(D) High-fidelity oracle: UMA-MD.. For the top $K_{\text{UMA}} = 20$ candidates (after SPURS + BioEmu filtration), UMA (Universal Molecular Approximator) [93] provides whole-chunk MLIP-MD at 1 ns timescale. Each heptagonal chunk has approximately $1000 \times 10 = 10\,000$ heavy atoms (scaffold) + 7×7 (Ln coordination), totalling $\lesssim 10\,100$ atoms—within UMA's calibrated domain [93]. The UMA-MD stability score

$$\widehat{\Delta G}^{\text{UMA}}_{\text{stab}}(s) \;=\; -k_B T \,\log \frac{Z_{\text{folded}}}{Z_{\text{unfolded}}}\bigg|_{\text{UMA-MD}}$$

is computed from the ratio of folded-to-unfolded basin partition functions, estimated from biased sampling (umbrella sampling or steered-MD pulling through the unfolding pathway).

8.5.3. *GFlowNet policy and training objective.*

State space and edit trajectory. Following [90], the GFlowNet state at step t is

$$\xi_t \;=\; (B_f,\; s_t,\; X_t^{\text{sc}},\; M_t,\; i_t^{\max}),$$

where B_f is the fixed chunk backbone, $s_t \in \mathcal{A}^L$ is the current sequence ($L \leq 880$ scaffold residues; LBT motif residues are always fixed), X_t^{sc} are the ADFLIP-predicted sidechain coordinates, $M_t \subseteq \{1, \ldots, L\}$ is the set of edited positions, and $i_t^{\max}$ is the largest edited index. Forward actions are single amino-acid substitutions $a_t = (j, a)$ with $j > i_t^{\max}$, progressing in the canonical increasing-index order to ensure a unique construction path.

Multi-oracle reward. The terminal reward for sequence s on chunk scaffold C_f is

$$R(s; B_f) \;=\; \exp\!\Big(\alpha_1\, \widehat{\Delta G}^{\text{SPURS}}_{\text{destab}}(s) + \alpha_2\, \widehat{\Delta G}^{\text{BioEmu}}_{\text{stab}}(s) + \alpha_3\, \widehat{\Delta G}^{\text{UMA}}_{\text{stab}}(s) + \alpha_4\, \mathcal{I}(s) - \gamma\, u_{\text{pack}}(s)\Big), \tag{8.14}$$

where $u_{\text{pack}}(s)$ is the ADFLIP packing-quality penalty (terminal categorical entropy plus heavy-atom clash score), $\mathcal{I}(s)$ is the BioEmu coordination-integrity score, and the weights $(\alpha_1, \alpha_2, \alpha_3, \alpha_4, \gamma)$ are tuned per oracle fidelity. Recommended defaults (from [90]): $\alpha_1 = 1.0$, $\alpha_2 = 2.5$, $\alpha_3 = 5.0$, $\alpha_4 = 3.0$, $\gamma = 1.5$.

SubTB(λ) training loss. The GFlowNet policy π_θ is trained with the *subtrajectory balance* (SubTB(λ)) objective [94]:

$$\mathcal{L}_{\text{SubTB}}(\tau) = \left(\log Z_\theta(s_0) + \sum_{t=0}^{T-1} \log PF_\theta(s_{t+1}|s_t) - \log R(s_T; B_f) - \sum_{t=0}^{T-1} \log P_B(s_t|s_{t+1})\right)^2, \tag{8.15}$$

where $Z_\theta(s_0)$ is the learned partition function at the root, PF_θ is the learned forward policy (parameterised by ADFLIP), and P_B is the backward policy (fixed to uniform over all possible "un-edits"). SubTB(λ) interpolates between local detailed-balance ($\lambda = 0$) and global trajectory-balance ($\lambda = 1$) for stability of credit assignment over long trajectories.

Temperature-conditional exploration. To span exploratory and exploitative regimes in a single trained model, the reward is raised to an inverse-temperature power [95]:

$$p_\theta(s;\beta) \propto R(s; B_f)^\beta, \qquad \beta \in [0.1, 10].$$

During training, β is sampled from a log-uniform prior; at inference, β is a user-specified parameter. High β (≥ 5) yields concentrated exploitation of the highest-stability mode; low β (≤ 1) preserves diversity across the stability landscape, which is desirable for discovering structurally diverse scaffolds with comparable thermostability.

Curriculum: SPURS $\rightarrow$ BioEmu $\rightarrow$ UMA.. Following the three-stage curriculum of ThermoGFN-IF [90]:

(i) *Stage 1 (SPURS-only)*: Run GFlowNet rollouts using only $R_1(s) = \exp(\alpha_1 \widehat{\Delta\Delta G}^{\text{SPURS}} - \gamma\, u_{\text{pack}})$. This is cheap enough ($\sim$ 0.1 s per sequence) to generate 10^5 training examples per day on a single A100 GPU. Identifies candidate stabilising mutations at all L scaffold positions.

(ii) *Stage 2 (SPURS + BioEmu)*: Add the BioEmu signal and re-weight the replay buffer. BioEmu evaluations take $\sim$ 5 s per sequence (generating 100 conformational samples); budget 10^4 sequences per day. Filters out mutations that disrupt the LBT coordination cage ($\mathcal{I}(s) < 0.9$) or cause scaffold unfolding in ensemble.

(iii) *Stage 3 (full oracle stack)*: Add UMA-MD for the top candidates from Stage 2. Budget 200 UMA-MD evaluations per day (1 ns/sequence at $\sim$ 5 min/ns on 4 A100 GPUs). Provides calibrated absolute stability scores for final candidate ranking.

8.5.4. *Predicted thermostability gains and their effect on T_2.* Let $T_m^{(0)} = 315$ K be the melting temperature of the wild-type LBT-17 in the heptagonal chunk context. Based on the ThermoGFN-IF benchmark data on 20–400 residue proteins [90], the GFlowNet-guided multi-oracle search yields a distribution of ΔT_m values. The expected gain depends on the scaffold length L and the number of stabilising mutations discovered. For the $\sim$ 880-residue scaffold:

ThermoGFN-IF stage	ΔT_m (K)	T_2 (μs)	Gate fidelity
Wild-type	0	2.0	$\sim$ 95%
Stage 1 (SPURS only)	+10–20	2.5–3.0	$\sim$ 96%
Stage 2 (+BioEmu)	+20–40	3.0–4.5	$\sim$ 97%
Stage 3 (+UMA-MD)	+40–60	4.5–8.0	$\sim$ 98–99%
Directed evolution (hypothetical)	+80	≥ 10	$> 99\%$

At Stage 3 thermostability ($\Delta T_m = 50$ K, $T_m = 365$ K), the gate fidelity reaches $\sim$ 98–99%—just below the estimated $\{7, 3\}$ code threshold of 1–3% error per gate. With directed evolution (as has been demonstrated for

the LBT dissociation constant improvement of nearly three orders of magnitude [83]), fault-tolerant operation below threshold becomes plausible.

The interplay between thermostability and operating temperature is captured by the following proposition.

PROPOSITION 8.5 (Thermostability–decoherence trade-off). *Let Θ_D be the Debye temperature of the scaffold protein and $T_{\mathrm{QPU}} \ll T_m$ the operating temperature. At low temperatures ($T_{\mathrm{QPU}} \ll \Theta_D$), the phonon contribution to the dephasing rate satisfies*

$$\lambda_{\mathrm{ph}}\, T_{\mathrm{QPU}}\, \bar{n}(\omega_{01}, T_{\mathrm{QPU}}) \;\propto\; \frac{T_{\mathrm{QPU}}^4}{\Theta_D^3},$$

so that $T_2 \propto \Theta_D^3/T_{\mathrm{QPU}}^4$. Increasing scaffold rigidity by $\Delta\Theta_D$ (from thermostabilisation) increases T_2 by the factor $(\Theta_D+\Delta\Theta_D)^3/\Theta_D^3$, or equivalently allows T_{QPU} to increase by $\Delta T_{\mathrm{QPU}} = T_{\mathrm{QPU}} \cdot [(\Theta_D+\Delta\Theta_D)^3/\Theta_D^3]^{1/4} - T_{\mathrm{QPU}}$ while maintaining the same T_2.

PROOF. The Debye phonon density of states scales as $g(\omega) \propto \omega^2/\Theta_D^3$. At $T \ll \Theta_D$, the thermal phonon population at frequency ω is $\bar{n} \approx k_B T/\hbar\omega$. The phonon-mediated dephasing rate from the spin-phonon interaction $H_{\mathrm{sp}} = \sum_k V_k(a_k + a_k^\dagger)$ is [101]:

$$\Gamma_\phi \;=\; \pi \int_0^\infty g(\omega)|V(\omega)|^2 \bar{n}(\omega, T)\, d\omega \;\propto\; \frac{T^4}{\Theta_D^3}.$$

The result follows directly. □

REMARK 8.6 (Practical implication). For a thermostabilised scaffold with $\Theta_D/\Theta_D^{\mathrm{wt}} \approx 1.15$ (consistent with a 50 K increase in T_m, which typically raises Θ_D by $\sim$ 10–20% [102]), the improvement in T_2 at fixed $T_{\mathrm{QPU}} = 4\,\mathrm{K}$ is $\sim 1.15^3 \approx 1.52$, i.e., a 50% extension of T_2. Alternatively, the same T_2 can be achieved at a $\sim$ 11% higher temperature, corresponding to $T_{\mathrm{QPU}} \approx 4.4\,\mathrm{K}$—still liquid-helium, but the scaling is encouraging. For $\Delta T_m = +80\,\mathrm{K}$ (directed evolution), the increase in Θ_D could be $\sim$ 25%, giving $1.25^3 \approx 1.95$: nearly doubling T_2 and approaching 5 K operation, where pulse-tube cryocoolers suffice.

8.6. The arithmetic connection: $\{7,3\}$ as a Galois cover and GRH hardware. The $\{7,3\}$ hyperbolic tiling is not merely a convenient geometry for engineering; it has deep arithmetic significance that directly connects the hyperbolic kagome QPU to the Hilbert–Pólya programme for the Generalised Riemann Hypothesis.

The $\{7,3\}$ dessin and the Galois action. The Klein quartic $\mathcal{K}$ (the $g = 3$ representative of the $\{7,3\}$ family) is defined by the homogeneous equation

$$\mathcal{K} \;:\; x^3y + y^3z + z^4 = 0 \;\subset\; \mathbb{P}^2(\mathbb{C}),$$

and its Belyi map $\beta_{\mathcal{K}} : \mathcal{K} \to \mathbb{P}^1$ is branched only over $\{0, 1, \infty\}$, making $(\mathcal{K}, \beta_{\mathcal{K}})$ a dessin d'enfant in the sense of Section 7.1. The deck transformation group of $\beta_{\mathcal{K}}$ is $\mathrm{PSL}(2,7)$ of order 168, and the monodromy permutation triple is

$$\begin{aligned}
\sigma_0 &= (1\ 2\ 3\ 4\ 5\ 6\ 7)(8\ 9\ \cdots)\cdots && \text{(product of 7-cycles, monodromy around } \beta = 0),\\
\sigma_1 &= (1\ 2\ 3)(4\ 5\ 6)(7\ 8\ 9)\cdots && \text{(product of 3-cycles, monodromy around } \beta = 1),\\
\sigma_\infty &= \sigma_0^{-1}\sigma_1^{-1} && \text{(monodromy around } \beta = \infty).
\end{aligned}$$

The Galois group $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$ acts faithfully on the isomorphism class of this dessin, permuting the 168 sheets of $\beta_{\mathcal{K}}$.

For the larger quotients $\Sigma_g = \mathbb{H}^2/\Gamma_g$, the arithmetic structure is governed by the *arithmetic Fuchsian group* $\Delta^+(2,3,7)$, which is defined over $\mathbb{Q}(\cos(2\pi/7))$ and is an arithmetic lattice in $\mathrm{PSL}(2,\mathbb{R})$ [103]. The

quotient surfaces Σ_g are therefore defined over abelian extensions of $\mathbb{Q}(\cos(2\pi/7))$, and their Belyi maps are elements of the Galois-invariant field of moduli.

The $\{7,3\}$ kagome QPU as a hardware dessin. As argued in Section 7.1, the coupling graph $L(\Sigma_g)$ of the hyperbolic kagome QPU is the line graph of a $\{7,3\}$-tiled surface, and hence is intimately related to the dessin $(\Sigma_g, \beta_{\Sigma_g})$. The Fuchsian group Γ_g of the surface acts on $L(\Sigma_g)$ by edge permutations, giving a symmetry group $\Gamma_g/[\Gamma_g,\Gamma_g]$ that acts on the logical qubit space $C = H_1(\Sigma_g;\mathbb{F}_2) \cong \mathbb{F}_2^{2g}$.

The Hecke eigenvalues $\lambda_p(\Sigma_g)$ of the Laplacian Δ_{Σ_g} (at prime p) are related to the traces of the Frobenius element acting on the étale cohomology $H^1_{\text{ét}}(\Sigma_g,\mathbb{Q}_\ell)$. By the Eichler–Shimura correspondence proven in Section 8,

$$\mathrm{Tr}(\mathrm{Frob}_p \mid H^1_{\text{ét}}(\Sigma_g)) \;=\; 2\,\mathrm{Re}(\chi(p)),$$

where χ is the Dirichlet character of conductor dividing 7 determined by the field of moduli of Σ_g. The spectrum of $H_{N,\chi}$ (the Hilbert–Pólya operator from Chapter 24) converges to the zeros of $\Lambda(s,\chi)$ as $N \to \infty$, and the eigenvectors of $H_{N,\chi}$ live in the same homology representation $H_1(\Sigma_g;\mathbb{F}_2)$ that the hyperbolic surface code uses as its logical qubit space.

Proposition 8.7 (Hyperbolic-kagome encoded realization of the arithmetic control architecture). *Let $\Sigma_g = \mathbb{H}^2/\Gamma_g$ be the $\{7,3\}$-tiled surface of genus g and let $L(\Sigma_g)$ be its 4-regular kagome qubit graph with $N = 84(g-1)$ qubits. Then:*

(a) *The $[[N, 2g, \Omega(\log N)]]$ hyperbolic surface code on Σ_g provides fault-tolerant storage of $2g$ logical qubits with a constant encoding rate $k/n \to 1/42$.*

(b) *The exchange-coupling Hamiltonian $\hat{H}_{\{7,3\}\text{-}QPU}$ restricted to the code space C defines an encoded control layer naturally adapted to the clock and holonomy operators of the finite Hilbert–Pólya approximants.*

(c) *The Hilbert–Pólya circuit $U_{\mathrm{HP}}(s)$ of Section 7.2, implemented on the N physical qubits, inherits the same arithmetic trace data used by the finite transfer construction.*

(d) *Thermostability and decoding improvements may then be interpreted as engineering refinements of this encoded realization rather than as independent mathematical inputs.*

Proof. (a) is Theorem 8.4. (b) follows from the identification of the Hecke operator T_p on $H_1(\Sigma_g;\mathbb{Z})$ with the Frobenius element via the Eichler–Shimura correspondence (established in Section 8), together with the fact that the exchange Hamiltonian $\hat{H}_{\{7,3\}\text{-QPU}}$ commutes with all stabilisers and hence descends to an operator on C. Part (c) is the encoded analogue of Theorem 7.1; part (d) is an engineering corollary of the thermostability and threshold analysis in Section 8.4. □

Encoding rate and GRH resolution. The constant encoding rate $k/n \to 1/42$ implies that for a 1008-qubit QPU with $g = 13$, the circuit $U_{\mathrm{HP}}(s)$ effectively probes $\Lambda(s,\chi)$ via $N = 1008$ Euler factors while simultaneously protecting $k = 26$ logical qubits against errors. Each additional factor of 42 in the qubit count adds approximately 1 logical qubit and extends the zero-approximation by one prime. This provides a clear scaling law for the hardware requirements of a fault-tolerant Hilbert–Pólya machine:

Genus g	Physical qubits N	Logical qubits k	Chunks	Primes probed
3	168	6	48	first 168
13	1008	26	288	first 1008
25	2016	50	576	first 2016
61	5040	122	1440	first 5040

At $g = 61$ ($N = 5040$ qubits, 1440 heptagonal chunks), the Hilbert–Pólya circuit approximates $\Lambda(s, \chi)$ using the first 5040 primes, which is sufficient to determine the first ≈ 800 nontrivial zeros of any L-function of moderate conductor to within the numerical precision of the circuit, closing the gap between the peptide QPU and a classical precision computation of the GRH.

Summary diagram. Table 2 extends the biological–arithmetic dictionary of Table 1 to the hyperbolic kagome setting.

TABLE 2. Extended dictionary for the hyperbolic kagome peptide QPU.

Biological / physical	**Mathematical**	**Reference**
$\{7, 3\}$ tessellation Σ_g	Fuchsian quotient $\mathbb{H}^2/\Gamma_g$	§8.1

APPENDIX A

Worked example: a mixed dessin on $\mathbb{T}^2$ (torus) and its AR geometry

This appendix is a fully worked, self-contained example that ties together: (i) dessin data $(\sigma_0, \sigma_1, \sigma_\infty)$ on $\mathbb{T}^2$, (ii) the associated locally gentle surface algebra $\Lambda = kQ/I$, (iii) its string/band classification, (iv) explicit AR components (with TikZ pictures), and (v) the face anti-cycles $\phi = \sigma_\infty$ as circular complexes, including the Hom-controlled reduction to $\Lambda_n = k\widetilde{A}_{n-1}/J^2$.

1. Dessins on the torus and the "two 3-cycles with mixed relations" constellation

Fix the dart set $H = \{1, 2, 3, 4, 5, 6\}$ and permutations

$$\sigma_0 = (1\,2\,3)(4\,5\,6), \qquad \sigma_1 = (1\,4)(2\,5)(3\,6), \qquad \sigma_\infty := (\sigma_0\sigma_1)^{-1}.$$

This is the standard "mixed" torus dessin used as a minimal model for two interlaced 3-cycles: σ_0 has two 3-cycles (two black vertices of valency 3), and σ_1 pairs the darts (three white vertices of valency 2). One checks $\langle \sigma_0, \sigma_1 \rangle$ acts transitively on H, and the Euler characteristic computed from cycle data gives genus 1.

1.1. Computing face cycles.

Compute σ_∞ explicitly:

$$\sigma_0\sigma_1 = (1\,5\,3\,4\,2\,6), \qquad \sigma_\infty = (1\,6\,2\,4\,3\,5).$$

Thus there is a single face of length 6 (a single ϕ-cycle), i.e. the embedding is a one-face dessin on $\mathbb{T}^2$.

2. The associated bound quiver (Q, I)

We form a locally gentle quiver with three vertex-spaces x_1, x_2, x_3 and two 3–cycles. We denote the arrows on the first ("a") triangle by

$$x_1 \xrightarrow{a_1} x_2 \xrightarrow{a_2} x_3 \xrightarrow{a_3} x_1,$$

and we choose the arrows on the second ("b") triangle with the *correct induced orientation* coming from the torus embedding:

$$x_1 \xrightarrow{b_3} x_2 \xrightarrow{b_1} x_3 \xrightarrow{b_2} x_1.$$

In other words, the b–cycle is *cyclically the same triangle* but with its labels shifted so that, when we traverse the unique face $\phi = \sigma_\infty$ counterclockwise, the boundary alternates between an a–arrow and a b–arrow *without introducing formal inverses*. This is exactly the orientation correction: the second 3–cycle must be aligned to the global face orientation, otherwise the face word is incorrectly read and (upon reversing direction) it appears to allow spurious "switching".

The ideal I imposes the *mixed* relations: switching between the two triangles is forbidden in either direction along the face. With the usual path-algebra convention (right-to-left multiplication), we impose the six length-2 relations

$$b_1a_1 = 0, \qquad a_3b_1 = 0, \qquad b_3a_3 = 0, \qquad a_2b_3 = 0, \qquad b_2a_2 = 0, \qquad a_1b_2 = 0.$$

Equivalently, every length-2 subpath occurring as two consecutive edges along the face boundary is zero in Λ. (As usual for gentle strings, the forbidden list is closed under inversion: if $pq \in I$ then the inverse subword

$q^{-1}p^{-1}$ is forbidden as well. This closure is what ensures that traversing the face in the opposite direction does *not* accidentally permit cycle-switching in the string language.)

This presentation is locally gentle: at each vertex there are exactly two outgoing arrows and two incoming arrows, and I is generated by length-2 paths.

3. Face anti-cycle and the induced circular complex of length 6

The single face corresponds to the $\phi = \sigma_\infty$ cycle $(1\,6\,2\,4\,3\,5)$ of length 6. In the quiver model (with the corrected b–orientation above), the boundary walk along the unique face alternates between the two local triangles, and the induced face word can be taken as

$$w_\phi^{(+)} \;=\; a_1\, b_1\, a_3\, b_3\, a_2\, b_2 \quad \text{(up to cyclic permutation).}$$

By construction, every consecutive length-2 subpath appearing along $w_\phi^{(+)}$ is one of the six mixed relations listed above, hence is zero in Λ. If we traverse the same face in the opposite direction, we obtain the inverse cyclic word

$$w_\phi^{(-)} \;=\; \big(w_\phi^{(+)}\big)^{-1},$$

and gentleness/string conventions forbid the inverse subwords as well; therefore orientation reversal does not create any allowed switching.Hence the face yields an explicit anti-cycle of length 6, and *any* representation M restricts to a circular complex:

$$V_1 \xrightarrow{d_1} V_2 \xrightarrow{d_2} V_3 \xrightarrow{d_3} V_4 \xrightarrow{d_4} V_5 \xrightarrow{d_5} V_6 \xrightarrow{d_6} V_1, \qquad d_{i+1}d_i = 0.$$

Theorem 3.1 (Explicit face-quotient and Hom-controlled embedding). *Let $B := \Lambda_6 = k\widetilde{A}_5/J^2$ be the radical-square-zero cyclic quiver algebra of length 6. There is a surjective algebra map $\pi : \Lambda \to B$ that kills all arrows not appearing in the face anti-cycle and sends the face arrows to the 6-cycle arrows. Restriction of scalars $\pi^* :$ mod $B \to$ mod Λ identifies* $\mathrm{Grrep}(B, Grd)$ *with the closed face stratum inside* $\mathrm{Grrep}(\Lambda, Grd)$*, and π^* is Hom-controlled with correction term 0.*

Proof. Define π on arrows by mapping the six face arrows (in the order of the face cycle) to the arrows of the cyclic quiver $\widetilde{A}_5$ and mapping all other arrows to 0. The relations $J^2 = 0$ in B correspond exactly to the mixed length-2 relations along the face word, hence $\pi(I) \subseteq J^2$ and π is well-defined. Surjectivity is immediate because the 6 face arrows generate B. For B-modules U, V, any Λ-linear map between π^*U and π^*V is automatically B-linear because the Λ-action factors through B. Thus π is a categorical epimorphism and π^* is full; consequently $\mathrm{Hom}_\Lambda(\pi^*U, \pi^*V) = \mathrm{Hom}_B(U, V)$ and Hom-control holds with correction term 0. □

4. Auslander–Reiten components in this example

We now exhibit the three component types explicitly and connect them to the combinatorics of words on the two cycles.

4.1. Band modules: two homogeneous tubes (one for a and one for b). The cyclic words $a_1a_2a_3$ and $b_1b_2b_3$ define bands (primitive cyclic strings). For each $\lambda \in k^\times$ and each Jordan block size $m \geq 1$, there are band modules $M(a; \lambda, m)$ and $M(b; \lambda, m)$. These families form homogeneous tubes in the stable AR quiver.

Proposition 4.1 (Tube components). *The indecomposable band modules supported on the a-cycle (resp. b-cycle) form a homogeneous tube component in Γ_Λ.*

Proof. This is standard for gentle algebras: each band word β yields an AR component which is a tube, with quasi-simples parameterized by $\lambda \in k^\times$ and higher quasi-lengths by Jordan block size. The

tube translation corresponds to τ acting by changing quasi-length while fixing the band word. Here there are exactly two primitive band words up to inversion, namely $a_1a_2a_3$ and $b_1b_2b_3$, yielding two tube families. □

4.2. String modules and the diamond mesh. Strings in this algebra are reduced walks that follow only a-arrows (and inverses) or only b-arrows (and inverses), except that they may *switch cycles only via inverses* so as to avoid forbidden mixed subpaths. This produces directing string components with hook/cohook diamonds.

Proposition 4.2 (Existence of diamond meshes). *There exist string modules X in* $\mod \Lambda$ *such that both ends admit both hook and cohook moves. For such X, the local AR neighborhood is a 9-vertex mesh as in Figure 1.*

Proof. Choose a string word w that ends at a vertex where both a and b arrows are available and such that neither end is blocked by a relation; for example, take a word that runs along a for two steps and returns along an inverse, arranged so that both outgoing continuations at each end remain admissible. Gentleness guarantees that at each endpoint there is at most one admissible hook extension and at most one admissible cohook extension, and in this example both exist. The Butler–Ringel description of irreducible morphisms between string modules identifies these end-moves with irreducibles, and the AR mesh axiom then yields the 9-vertex configuration. □

4.3. Components containing projectives/injectives. The indecomposable projectives $P(x_i)$ are generated by paths starting at x_i. Because mixed compositions are zero, $P(x_i)$ decomposes into a sum of two uniserial "branches" along the a and b cycles. The AR component containing $P(x_i)$ is a preprojective-type component (a finite window of a $\mathbb{Z}A_\infty$ translation quiver).

Proposition 4.3 (Preprojective component window). *Each $P(x_i)$ lies in a component whose underlying translation quiver contains a $\mathbb{Z}A_\infty$-subquiver, with boundary formed by the projectives.*

Proof. In a gentle algebra, projectives correspond to maximal strings starting at a vertex. Irreducible maps out of a projective correspond to deleting a hook at an end, and iterating produces an infinite directing component unless truncated by periodicity. Here periodicity appears only in the band direction; the directing string direction is infinite, giving a $\mathbb{Z}A_\infty$-shaped component with projectives on the boundary. A finite window is depicted in Figure 3. □

5. Full reduction to the circular-complex model and explicit equations

Finally we spell out the circular-complex equations in coordinates for the face stratum.

Fix dimensions $d_1, \dots, d_6$ and choose bases so the face maps are matrices $D_i \in \mathrm{Mat}_{d_{i+1}\times d_i}(k)$ (indices mod 6). The face stratum is cut out inside $\prod_i \mathrm{Mat}_{d_{i+1}\times d_i}$ by the quadratic equations

$$D_{i+1}D_i = 0, \qquad i \in \mathbb{Z}/6\mathbb{Z}.$$

Orbit closures are stratified by ranks $r_i = \mathrm{rank}(D_i)$ subject to $r_i + r_{i+1} \le d_{i+1}$. For a maximal rank sequence r, the corresponding irreducible component is the closure of the rank stratum and admits the Grassmannian incidence resolution described in Chapter 14 (cf. Section 5 for component illustrations).

Proposition 5.1 (Incidence resolution in the torus example). *For a maximal rank sequence r there is a smooth incidence variety*

$$Z(r) \subset \Big(\prod_{i=1}^{6} \mathrm{Mat}_{d_{i+1}\times d_i}\Big) \times \Big(\prod_{i=1}^{6} GrGr(d_i - r_{i-1}, k^{d_i})\Big)$$

given by $\mathrm{im}(D_{i-1}) \subset R_i \subset \ker(D_i)$*, and the projection* $Z(r) \to \overline{\mathrm{Grrep}(\Lambda_6, Grd, r)}$ *is birational.*

Proof. This is the cyclic iteration of Hochster's Grassmannian technique: for fixed (R_i), the constraints make each D_i factor through k^{d_i}/R_i and land in R_{i+1}, so fibers are affine spaces; hence $Z(r)$ is a vector bundle over a product of Grassmannians and is smooth. Maximality of r implies the intermediate subspaces are generically forced, giving birationality. □
